an otherwise healthy person presents with an acute or subacute episode of paresthesias, optic neuritis (i.e., visual clouding or loss of vision in part of the visual field with pain on movement of the globe), diplopia, or specific types of gaze paralysis.

Ms. Ulrie presented with blurry vision in the right eye, which is indicative of optic neuritis. She had been feeling fine until a week ago when she experienced this acute episode of symptoms. The symptoms persisted, so she went to the emergency department. At 22 years of age she may have had the MS for a while given that she had one or two plaques already as illustrated in her MRI.

Paresthesias are evidenced as numbness, tingling, burning sensations, or pressure on the face or involved extremities, with symptoms ranging from annoying to severe. Pain from spasticity also may be a factor that can be alleviated by appropriate stretching exercises. Other common symptoms are abnormal gait, bladder and sexual dysfunction, vertigo, nystagmus, fatigue, and speech disturbance. These symptoms usually last for several days to weeks and then completely or partially resolve. After a period of normal or relatively normal function, new symptoms appear. Psychological manifestations, such as mood swings, may represent an emotional reaction to the nature of the disease or, more likely, involvement of the white matter of the cerebral cortex. Depression, euphoria, inattentiveness, apathy, forgetfulness, and loss of memory may occur. Fatigue is one of the most common problems for people with MS. Fatigue often is described as a generalized low-energy feeling not related to depression and different from weakness. Fatigue has a harmful impact on activities of daily living and sustained physical activity. Interventions such as spacing activities and setting priorities often are helpful.

The course of the disease may fall into one of four categories:

1. Relapsing–remitting
2. Secondary progressive
3. Primary progressive
4. Progressive relapsing

The relapsing–remitting form of the disease is characterized by episodes of acute worsening with recovery and a stable course between relapses.

It will be difficult for Ms. Ulrie if she progresses to having speech disturbances; mood swings, which would indicate white matter involvement; forgetfulness; and loss of memory as a college student. She is very fatigued, which is another frequent symptom, and she will need to have some assistance in planning her hectic course schedule so she can manage it. Ms. Ulrie was diagnosed with the relapsing–remitting form of MS so she should have some stable times in between exacerbations if she is able to organize herself and get adequate rest. This will indeed be difficult as a college student.

Secondary progressive disease involves a gradual neurologic deterioration with or without superimposed acute relapses in a person with previous relapsing–remitting disease. Primary progressive disease is characterized by nearly continuous neurologic deterioration from onset of symptoms. The progressive relapsing category of disease involves gradual neurologic deterioration from the onset of symptoms but with subsequent superimposed relapses.

Diagnosis

The diagnosis of MS is based on established clinical and, when necessary, laboratory criteria. There is no one definitive diagnostic test. Advances in cerebrospinal fluid (CSF) analysis and MRI have greatly simplified the procedure. A definite diagnosis of MS requires evidence of one of the following patterns:

- Two or more episodes of exacerbation separated by 1 month or more and lasting more than 24 hours, with subsequent recovery
- A clinical history of clearly defined exacerbations and remissions, with or without complete recovery, followed by progression of symptoms over a period of at least 6 months
- Slow and stepwise progression of signs and symptoms over a period of at least 6 months

With a more detailed history taking session, the neurologist was able to determine that Ms. Ulrie had had similar symptoms, but especially visual blurriness about 6 months prior to this event. She said she had just taken it easy and rested since it was during the summer and all of the symptoms went away. She had not seen a physician for this previous episode because she felt it was due to stress of the previous academic year. She also did not have the fatigue that she has now nor was the blurriness as bad in her eye.

Primary progressive MS may be suggested by a progressive course that lasts longer than 6 months. A person who has not had a relapse or progression of symptoms is described as having stable MS.

MRI can be used as an adjunct to clinical diagnosis. MRI studies can detect lesions even when CT scans appear normal. A computer-assisted method of MRI can measure lesion size. Many new areas of myelin abnormality are asymptomatic. Serial MRI studies can be done to detect asymptomatic lesions, monitor the progress of existing lesions, and evaluate the effectiveness of treatment. Although MRI can be used to provide evidence of disseminated lesions in people with the disease, normal findings do not exclude the diagnosis. Electrophysiologic evaluations (e.g., evoked potential studies) and CT scans may assist in the identification and documentation of lesions.

Although no laboratory test can be used to diagnose MS, examination of the CSF is helpful. A large percentage of people with MS have elevated immunoglobulin G (IgG) levels,
and some have oligoclonal patterns (i.e., discrete electrophoretic bands) even with normal IgG levels. Total protein or lymphocyte levels may be mildly elevated in the CSF. These test results can be altered in a variety of inflammatory neurologic disorders and are not specific for MS.

The CSF from the lumbar puncture results are protein 0.40/L, lymphocytes $3 \times 10^6$/L, and oligoclonal bands present. Oligoclonal bands are not found in normal CSF, but are found in 90% of people with MS. So these results added to the confirmation of the diagnosis for Ms. Ulrie.

**Treatment**

Most treatment measures for MS are directed at modifying the course and managing the primary symptoms of the disease. The variability in symptoms, unpredictable course, and lack of specific diagnostic methods have made the evaluation and treatment of MS difficult. People who are minimally affected by the disorder require no specific treatment. The person should be encouraged to maintain as healthy a lifestyle as possible, including good nutrition and adequate rest and relaxation. Physical therapy may help maintain muscle tone. Every effort should be made to avoid excessive fatigue, physical deterioration, emotional stress, viral infections, and extremes of environmental temperature, which may precipitate an exacerbation. The pharmacologic agents used in the management of MS fall into three categories:

1. Those used to treat acute attacks or initial demyelinating episodes
2. Those used to modify the course of the disease
3. Those used to treat symptoms of the disorder

Corticosteroids are the mainstay of treatment for acute attacks of MS. These agents are thought to reduce the inflammation, improve nerve conduction, and have important immunologic effects. Long-term administration does not, however, appear to alter the course of the disease and can have harmful side effects. Plasmapheresis and intravenous immunoglobulin have also proven beneficial in some cases.

The agents used to modify the course of the disease include interferon beta, glatiramer acetate, and mitoxantrone. These agents have shown some benefit in reducing exacerbations in persons with relapsing–remitting MS. Interferon beta is a cytokine that acts as an immune enhancer. Interferon is administered by injection and is usually well tolerated. The most common side effects are flulike symptoms for 24 to 48 hours after each injection, and these usually subside after 2 to 3 months of treatment. Glatiramer acetate is a synthetic polypeptide that simulates parts of the myelin basic protein. Although the exact mechanism of action is unknown, the drug seems to block myelin-damaging T cells by acting as a myelin decoy. The drug is given daily by subcutaneous injection.

Mitoxantrone is an antineoplastic agent that prevents the ligation of DNA strands and thus delays the cell-cycle progression and has immunomodulatory properties. Acute drug side effects include nausea and alopecia. Recently, a humanized monoclonal antibody, natalizumab, has also been approved for relapsing–remitting MS. Its action is suppression of leukocyte entry into the CNS.

Among the medications used to manage the chronic problems associated with MS are dantrolene, baclofen, or diazepam for spasticity; cholinergic drugs for bladder problems; and antidepressant drugs for depression. A high-fiber diet is recommended for people with MS who experience constipation.

**Vertebral and Spinal Cord Injury**

SCI represents damage to the neural elements of the spinal cord. SCI is primarily a disorder of young people, with most injuries occurring in the 16- to 32-year age group. In the United States, there are 250,000 people with spinal cord injuries. The most common cause of SCI is motor vehicle accidents, followed by violence (primarily gunshot wounds), falls, and recreational sporting activities. Life expectancy for people with SCI continues to increase, but is somewhat below life expectancy for those without SCI. Mortality rates are significantly higher during the first year after injury than during subsequent years, particularly for severely injured people.

Most SCIs involve damage to the vertebral column or supporting ligaments as well as the spinal cord. Because of extensive tract systems that connect sensory afferent neurons and LMNs with high brain centers, SCIs commonly involve both sensory and motor function. Although the discussion in this section of the chapter focuses on traumatic SCI, much of the content is applicable to SCI caused by other disorders, such as congenital deformities (e.g., spina bifida), tumors, ischemia and infarction, and bone disease with pathologic fractures of the vertebrae.

**Injury to the Vertebral Column**

Injuries to the vertebral column include fractures, dislocations, and subluxations. A fracture can occur at any part of the bony vertebrae, causing fragmentation of the bone. It most often involves the pedicle, lamina, or processes (e.g., facets). Dislocation or subluxation (partial dislocation) injury causes the vertebral bodies to become displaced, with one overriding another and preventing correct alignment of the vertebral column. Damage to the ligaments or bony vertebrae may make the spine unstable. In an unstable spine, further unguarded movement of the spinal column can impinge on the spinal canal, causing compression or overstretching of neural tissue.

Most SCI injuries occur due to a combination of wrenching movements and a compressive force. Flexion injuries (i.e., hyperflexion) occur when forward bending of the spinal column exceeds the limits of normal movement. Typical flexion injuries result, for example, when the head is struck from behind, as in a fall with the back of the head as the point of
Sudden, complete transection of the spinal cord results in complete loss of motor, sensory, reflex, and autonomic function below the level of injury. The immediate response to SCI is often referred to as spinal shock. It is characterized by flaccid paralysis with loss of tendon reflexes below the level of injury, absence of somatic and visceral sensations below the level of injury, and loss of bowel and bladder function. Loss of systemic sympathetic vasomotor tone may result in vasodilation, increased venous capacity, and hypotension. These manifestations occur regardless of whether the level of the lesion eventually will produce spastic (UMN) or flaccid (LMN) paralysis. The basic mechanisms accounting for transient spinal shock are unknown. Spinal shock may last for hours, days, or weeks. Usually, if reflex function returns by the time the person reaches the hospital, the neuromuscular changes are reversible. This type of reversible spinal shock may occur in football-type injuries, in which jarring of the spinal cord produces a concussion-like syndrome with loss of movement and reflexes, followed by full recovery within days. In people in whom the loss of reflexes persists, hypotension and bradycardia may become critical but manageable problems. In general, the higher the level of injury (i.e., T6 and above), the greater is the effect.

**Pathophysiology.** The pathophysiology of acute SCI can be divided into two types—primary and secondary. The primary neurologic injury occurs at the time of mechanical injury and is irreversible. It is characterized by small hemorrhages in the gray matter of the cord, followed by edematous changes in the white matter that lead to necrosis of neural tissue. This type of injury results from the forces of compression, stretch, and impact. Extension injuries occur with excessive forced bending (i.e., hyperextension) of the spine backward. A typical extension injury involves a fall in which the chin or face is the point of impact, causing hyperextension of the neck. Injuries of flexion and extension occur more commonly in the cervical spine (C4 to C6) than in any other area. Limitations imposed by the ribs, spinous processes, and joint capsules in the thoracic and lumbar spine make this area less flexible and less susceptible to flexion and extension injuries than the cervical spine.

A compression injury, causing the vertebral bones to shatter, squash, or even burst, occurs when there is spinal loading (i.e., axial load) from a high-velocity blow to the top of the head, such as a diving injury (Fig. 19.14A). Compression injuries may occur when the vertebralbe are weakened by conditions such as osteoporosis and cancer with bone metastasis. Axial rotation injuries can produce highly unstable injuries. Maximal axial rotation occurs in the cervical region, especially between C1 and C2, and at the lumbosacral joint (Fig. 19.14B). Coupling of vertebral motions is common in injury when two or more individual motions occur (e.g., lateral bending and axial rotation).

**Acute Spinal Cord Injury**

SCI involves damage to the neural elements of the spinal cord. The damage may result from direct trauma to the cord from penetrating wounds or indirect injury resulting from vertebral fractures, fracture–dislocations, or subluxations of the spine. The spinal cord may be contused, not only at the site of injury but above and below the trauma site causing it to swell. Traumatic injury may be complicated by the loss of blood flow to the cord, with resulting infarction.

**FIGURE 19.14** • (A) Compression vertebral fracture secondary to axial loading as occurs when a person falls from a height and lands on the buttocks. (B) Rotational injury, in which there is concurrent fracture and tearing of the posterior ligamentous complex, is caused by extreme lateral flexion or twisting of the head or neck. (From Morton P. G., Fontaine D. K. (2009). *Critical care nursing: A holistic approach* (9th ed., p. 941). Philadelphia, PA: Lippincott Williams & Wilkins.)
shear associated with fracture or compression of the spinal vertebrae, dislocation of vertebrae (e.g., flexion, extension, subluxation), and contusions due to jarring of the cord in the spinal canal. Penetrating injuries produce lacerations and direct trauma to the cord and may occur with or without spinal column damage. Lacerations occur when there is cutting or tearing of the spinal cord, which injures nerve tissue and causes bleeding and edema.

**Secondary injuries** follow the primary injury and promote the spread of injury. Although there is considerable debate about the pathogenesis of secondary injuries, the tissue destruction that occurs ends in progressive neurologic damage. After SCI, several pathologic mechanisms come into play, including vascular damage, neuronal injury that leads to loss of reflexes below the level of injury, and release of vasoactive agents and cellular enzymes. Vascular lesions (i.e., vessel trauma and hemorrhage) can lead to ischemia, increased vascular permeability, and edema. Blood flow to the spinal cord may be further compromised by spinal shock that results from a loss of vasomotor tone and neural reflexes below the level of injury. The release of vasoactive substances (i.e., norepinephrine, serotonin, dopamine, and histamine) from the wound tissue causes vasospasm and impedes blood flow in the microcirculation, producing further necrosis of blood vessels and neurons. The release of proteolytic and lipolytic enzymes from injured cells causes delayed swelling, demyelination, and necrosis in the neural tissue in the spinal cord.

**Treatment.** The goal of management of acute SCI is to reduce the neurologic deficit and prevent any additional loss of neurologic function. Most traumatic injuries to the spinal column render it unstable, mandating measures such as immobilization with collars and backboards and limiting the movement of people at risk for, or with known, SCI. Every person with multiple trauma or head injury is automatically treated as if he or she has a cervical cord injury until this is ruled out with imaging.

The nature of the injury determines further methods of stabilization and treatment. In unstable injuries of the cervical spine, cervical traction improves or restores spinal alignment, decompresses neural structures, and facilitates recovery. Fractures and dislocations of the thoracic and lumbar vertebrae may be initially stabilized by restricting the person to bed rest and turning him or her in a logrolling manner to keep the spine rigid. Gunshot or stab wounds of the spinal column may not produce structural instability and may not require immobilization.

The goal of early surgical intervention for an unstable spine is to provide internal skeletal stabilization so that early mobilization and rehabilitation can occur. One of the more important aspects of early SCI care is the prevention and treatment of spinal or systemic shock and the hypoxia associated with compromised respiration. The cord must be perfused in order to prevent hypoxia. Early treatment with high-dose methylprednisolone can be considered for use with the intent of improving neurologic recovery. Methylprednisolone is a short-acting corticosteroid that has been used extensively in the treatment of inflammatory and allergic disorders. In acute SCI, it is thought to stabilize cell membranes, enhance impulse generation, improve blood flow, and inhibit free radical formation. However, methylprednisolone treatment remains controversial in many countries.

**Types and Classification of Spinal Cord Injury**

Alterations in body function that result from SCI depend on the level of injury and the amount of cord involvement. *Tetraplegia*, sometimes referred to as *quadriplegia*, is the impairment or loss of motor or sensory function (or both) after damage to neural structures in the cervical segments of the spinal cord. It results in impairment of function in the arms, trunk, legs, and pelvic organs. *Paraplegia* refers to impairment or loss of motor or sensory function (or both) in the thoracic, lumbar, or sacral segments of the spinal cord from damage of neural elements in the spinal canal. With paraplegia, arm functioning is spared, but depending on the level of injury, functioning of the trunk, legs, and pelvic organs may be impaired. Paraplegia includes conus medullaris and cauda equina injuries.

Further definitions of SCI describe the extent of neurologic damage as *complete* or *incomplete*. Complete cord injuries can result from severance of the cord, disruption of nerve fibers although they remain intact, or interruption of blood supply to that segment, resulting in complete destruction of neural tissue and UMN or LMN paralysis. With complete injuries, no motor or sensory function is preserved in sacral segments S4 to S6. Incomplete SCI implies there is some residual motor or sensory function below the level of injury. The prognosis for return of function is better in an incomplete injury because of preservation of axonal function. Incomplete injuries may manifest in a variety of patterns, but can be organized into certain patterns or “syndromes” that occur more frequently and reflect the predominant area of the cord that is involved. Types of incomplete lesions include the central cord syndrome, anterior cord syndrome, Brown-Séquard syndrome, and conus medullaris syndrome.

**Central Cord Syndrome.** A condition called *central cord syndrome* occurs when injury is predominantly in the central gray or white matter of the cord (Fig. 19.15A). Because the corticospinal tract fibers are organized with those controlling the arms located more centrally and those controlling the legs located more laterally, some external axonal transmission may remain intact. Motor function of the upper extremities is affected, but the lower extremities may not be affected or may be affected to a lesser degree, with some sparing of sacral sensation. Bowel, bladder, and sexual functions usually are affected to various degrees, and this may parallel the degree of lower extremity involvement. This syndrome occurs almost exclusively in the cervical cord, rendering the lesion a UMN lesion with spastic paralysis. Central cord damage is more frequent in older adults with narrowing or stenotic changes in the spinal canal that are related to arthritis. Damage also may occur in people with congenital stenosis.
Brown-Séquard Syndrome. A condition called Brown-Séquard syndrome results from damage to a hemisection of the anterior and posterior cord (Fig. 19.15B). The effect is an ipsilateral loss of voluntary motor function from the corticospinal tract and proprioception loss with a contralateral loss of pain and temperature sensation from the lateral spinothalamic tracts for all levels below the lesion.

Anterior Cord Syndrome. Anterior cord syndrome usually is caused by damage from infarction of the anterior spinal artery, resulting in damage to the anterior two thirds of the cord (Fig. 19.15C). The deficits include loss of motor function provided by the corticospinal tracts and loss of pain and temperature sensation from the lateral spinothalamic tracts. The posterior one third of the cord is relatively unaffected, preserving the dorsal column axons that convey position, vibration, and touch sensation.

Conus Medullaris and Cauda Equina Syndromes. The conus medullaris syndrome involves damage to the conus medullaris or the sacral cord (i.e., T12 to L1, lower end of spinal cord) and lumbar nerve roots in the neural canal. Functional deficits resulting from this type of injury usually result in flaccid bowel and bladder and altered sexual function. Sacral segments occasionally show preserved reflexes if only the conus is affected. Motor function in the legs and feet may be impaired without significant sensory impairment. The cauda equina syndrome occurs when damage to the lumbo-sacral nerve roots (i.e., L1 to L2) in the spinal canal usually results in LMN and sensory neuron damage. Functional deficits present as various patterns of asymmetric flaccid paralysis, sensory impairment, and severe, asymmetric pain. Due to the possible permanent neurological damage, emergent surgery is indicated for cauda equina syndrome.

Disruption of Somatosensory and Skeletal Muscle Function

Functional abilities after SCI are subject to various degrees of somatosensory and skeletal muscle function loss and altered reflex activity based on the level of cord injury and extent of cord damage (Table 19.2).

Motor and Somatosensory Function. Motor function in cervical injuries ranges from complete dependence to independence with or without assistive devices in activities of mobility and self-care. The functional levels of cervical injury are related to C5, C6, C7, or C8 innervation. At the C5 level, deltoid and biceps function is spared, allowing full head, neck, and diaphragm control with good shoulder strength and full elbow flexion. At the C6 level, wrist dorsiflexion by the wrist extensors is functional, allowing tenodesis, which is the natural bending inward and flexion of the fingers when the wrist is extended and bent backward. Tenodesis is a key movement because it can be used to pick up objects when finger movement is absent. A functional C7 injury allows full elbow flexion and extension, wrist plantar flexion, and some finger control. At the C8 level, finger flexion is added.

Thoracic cord injuries (T1 to T12) allow full upper extremity control with limited to full control of intercostal and trunk muscles and balance. Injury at the T1 level allows full fine motor control of the fingers. Because of the lack of specific functional indicators at the thoracic levels, the level of injury usually is determined by sensory level testing.

Functional capacity in the L1 through L5 nerve innervations allows hip flexion, hip abduction (L1 to L3), movement of the knees (L2 to L5), and ankle dorsiflexion (L4 to L5). Sacral (S1 to S5) innervation allows for full leg, foot, and ankle control and innervation of perineal musculature for bowel, bladder, and sexual functions.

Reflex Activity. Spinal cord reflexes are fully integrated in the spinal cord and can function independent of input from higher centers. Altered spinal reflex activity after SCI is essentially determined by the level of injury and whether UMN or LMN are affected. With UMN injuries at T12 and above, the cord reflexes remain intact, whereas communication pathways with higher centers have been interrupted. This results in spasticity of involved skeletal muscle groups and of smooth and skeletal muscles that control bowel, bladder, and sexual functions. In LMN injuries at T12 or below, the reflex circuitry itself has been damaged at the level of the spinal cord or spinal nerve, resulting in a decrease or absence of reflex function. The LMN injuries cause flaccid paralysis of involved skeletal muscle groups and the smooth and skeletal muscles that control bowel, bladder, and sexual functions. However, injuries near the T12 level may
result in mixed UMN and LMN deficits (e.g., spastic paralysis of the bowel and bladder with flaccid muscle tone).

After the period of spinal shock in a UMN injury, isolated spinal reflex activity and muscle tone that is not under the control of higher centers return. This may result in hypertonia and spasticity of skeletal muscles below the level of injury. These spastic movements are involuntary instead of voluntary, a distinction that needs to be explained to people with SCI and their families. The antigravity muscles, the flexors of the arms and extensors of the legs, are predominantly affected. The stimuli for reflex muscle spasm arise from somatic and visceral afferent pathways that enter the cord below the level of injury. The most common of these stimuli are muscle stretching, bladder infections or stones, fistulas, bowel distention or impaction, pressure areas or irritation of the skin, and infections. Because the stimuli that precipitate spasms vary from person to person, careful assessment is necessary to identify the factors that precipitate spasm in each person. Passive range-of-motion exercises to stretch the spastic muscles help to prevent spasm induced by muscle stretching, such as occurs with a change in body position.

Spasticity in itself is not detrimental and may even facilitate maintenance of muscle tone to prevent muscle wasting, improve venous return, and aid in mobility. Spasms become detrimental when they impair safety. They also reduce the ability to make functional gains in mobility and activities of daily living. Spasms also may cause trauma to bones and tissues, leading to joint contractures and skin breakdown.

**Respiratory Muscle Function.** In order for ventilation to occur, the expiratory and inspiratory muscles need to be innervated by the spinal cord. Segments C3 to C5 through the phrenic nerves innervate the main muscle of ventilation, the diaphragm. Spinal segments T1 through T7 innervate the intercostal muscles, which function in elevating the rib cage and are needed for coughing and deep breathing. The major muscles of expiration are the abdominal muscles, which receive their innervation from levels T6 to T12.

Although the ability to inhale and exhale may be preserved at various levels of SCI, functional deficits in ventilation are most apparent in the quality of the breathing cycle and the ability to oxygenate tissues, eliminate carbon dioxide, and mobilize secretions. Cord injuries involving C1 to C3 result in a lack of respiratory effort, and affected people require assisted ventilation. Although a C3 to C5 injury allows partial or full diaphragmatic function, ventilation is diminished because of the loss of intercostal muscle function, resulting in shallow breaths and a

*Assistance refers to adaptive.
weak cough. Below the C5 level, as less intercostal and abdominal musculature is affected, the ability to take a deep breath and cough is less impaired. Maintenance therapy consists of muscle training to strengthen existing muscles for endurance and mobilization of secretions. The ability to speak is compromised with assisted ventilation, whether continuous or intermittent. Thus, ensuring adequate communication of needs is also essential.

**Disruption of Autonomic Nervous System Function**

If there is an SCI, all autonomic nerve function below the injury site will be stopped. This includes sympathetic outflow from the thoracic and lumbar cord and parasympathetic outflow from the sacral cord. Because of their sites of exit from the CNS, the cranial nerves, such as the vagus, are unaffected. Depending on the level of injury, the spinal reflexes that control autonomic nervous system function are largely isolated from the rest of the CNS. Afferent sensory input that enters the spinal cord is unaffected, as is the efferent motor output from the cord. Lacking are the regulation and integration of reflex function by centers in the brain and brain stem. This results in a situation in which the autonomic reflexes below the level of injury are uncontrolled, whereas those above the level of injury function in a relatively controlled manner.

Sympathetic nervous system regulation of circulatory function and body temperature (i.e., thermoregulation) presents some of the most severe problems in SCI. The higher the level of injury and the greater the surface area affected, the more profound are the effects on circulation and thermoregulation. People with injury at the T6 level or above experience problems in regulating vasomotor tone. Those with injuries below the T6 level usually have sufficient sympathetic function to maintain adequate vasomotor function. The level of injury and its corresponding problems may vary among people, and some dysfunctional effects may be seen at levels below T6. With lower lumbar and sacral injuries, sympathetic function remains essentially unaltered.

**Vasovagal Response.** The vagus nerve (cranial nerve X), which is unaffected in SCI, normally exerts a continuous inhibitory effect on heart rate. Vagal stimulation that causes a marked bradycardia is called the *vasovagal response*. Visceral afferent input to the vagal centers in the brain stem of people with tetraplegia or high-level paraplegia can produce marked bradycardia when unchecked by a dysfunctional sympathetic nervous system. Severe bradycardia and even asystole can result when deep endotracheal suctioning or rapid position change elicits the vasovagal response. Preventive measures, such as hyperoxygenation before, during, and after suctioning, are advised. Rapid position changes should be avoided or anticipated, and anticholinergic drugs should be immediately available to counteract severe episodes of bradycardia.

**Autonomic Dysreflexia.** Autonomic dysreflexia, also known as autonomic hyperreflexia, represents an acute episode of exaggerated sympathetic reflex responses that occur in people with injuries at T6 and above, in which CNS control of spinal reflexes is lost (Fig. 19.16). It does not occur until spinal shock has resolved and autonomic reflexes return, most often within the first 6 months after injury. It is most unpredictable during the first year after injury, but can occur throughout the person’s lifetime.

Autonomic dysreflexia is characterized by mild to severe hypertension, skin pallor, and gooseflesh associated with the piloerector response. Because baroreceptor function and parasympathetic control of heart rate travel by way of the cranial nerves, these responses remain intact. Continued hypertension produces a baroreflex-mediated vagal slowing of the heart rate to bradycardic levels. There is an accompanying baroreflex-mediated vasodilation, with flushed skin and profuse sweating above the level of injury, headache ranging from dull to severe and pounding, nasal stuffiness, and feelings of anxiety. A person may experience one, several, or all of the symptoms with each episode.

The stimuli initiating the dysreflexic response include visceral distention, such as a full bladder or rectum; stimulation of pain receptors, as occurs with pressure ulcers, ingrown toenails, dressing changes, and diagnostic or operative procedures; and visceral contractions, such as ejaculation, bladder spasms, or uterine contractions. In many cases, the dysreflexic response results from a full bladder.

Autonomic dysreflexia is a clinical emergency, and without prompt and adequate treatment, convulsions, loss of consciousness, and even death can occur. The major components of treatment include monitoring blood pressure while removing or correcting the initiating cause or stimulus. The person should be placed in an upright position, and all support hose or binders should be removed to promote venous pooling of blood and reduce venous return, thereby decreasing blood pressure. If the stimuli have been removed or the stimuli cannot be identified and the upright position is established, but the blood pressure remains elevated, drugs that block autonomic function are administered. Prevention of the type of stimuli that trigger the dysreflexic event is advocated.

**Postural Hypotension.** Postural, or orthostatic, hypotension can occur with injuries at T4 to T6 and above and is due to the interruption of sympathetic outflow to blood vessels in the extremities and abdomen. Pooling of blood, along with gravitational forces, impairs venous return to the heart, and there is a subsequent decrease in cardiac output when the person is placed in an upright position. The signs of orthostatic hypotension include dizziness, pallor, excessive sweating above the level of the lesion, complaints of blurred vision, and possibly fainting. Postural hypotension usually is prevented by slow changes in position and measures to promote venous return.

**Disruption of Bladder, Bowel, and Sexual Functions**

Loss of bladder function results from disruption of neural pathways between the bladder and the reflex voiding center at the S2 to S4 level (i.e., an LMN lesion) or between the reflex voiding center and higher brain centers for communication and coordinated sphincter control (i.e., a UMN lesion). People with
UMN lesions or spastic bladders lack awareness of bladder filling (i.e., storage) and voluntary control of voiding (i.e., evacuation). In LMN lesions or flaccid bladder dysfunction, lack of awareness of bladder filling and lack of bladder tone render the person unable to void voluntarily or involuntarily.

Bowel elimination is a coordinated function involving the enteric nervous system, the autonomic nervous system, and the CNS. Persons with SCI above S2 to S4 develop spastic functioning of the defecation reflex and loss of voluntary control of the external anal sphincter. Damage to the cord at the S2 to S4 level causes flaccid functioning of the defecation reflex and loss of anal sphincter tone. Even though the enteric nervous system innervation of the bowel remains intact, without the defecation reflex, peristaltic movements are ineffective in evacuating stool.

Sexual function, like bladder and bowel control, is mediated by the S2 to S4 segments of the spinal cord. The genital sexual response in SCI, which is manifested by an erection in men and vaginal lubrication in women, may be initiated by mental or touch stimuli, depending on the level of injury. The T11 to L2 cord segments have been identified as the mental-stimulus, or psychogenic, sexual response area, where autonomic nerve pathways in communication with the forebrain leave the cord and innervate the genitalia. The T11 to L2 cord segments have been identified as the mental-stimulus, or psychogenic, sexual response area, where autonomic nerve pathways in communication with the forebrain leave the cord and innervate the genitalia. The S2 to S4 cord segments have been identified as the sexual-touch reflex center. In T10 or higher injuries, reflex sexual response to genital touch may occur freely. However, a sexual response to mental stimuli (T11 to L2) does not occur because of the spinal lesion blocking the communication pathway. In an injury at T12 or below, the sexual reflex center may be damaged, and there may be no response to touch.

In men, the lack of erectile ability or inability to experience penile sensations or orgasm is not a reliable indicator of fertility, which should be evaluated by an expert. In women, fertility is parallel to menses. Usually, it is delayed 3 to 5 months after injury.
Deep Vein Thrombosis and Edema. People with SCI are at high risk for development of deep vein thrombosis (DVT) and pulmonary embolism. The high risk for DVT in people with acute SCI is due to immobility, decreased vasomotor tone below the level of injury, and hypercoagulability and stasis of blood flow. Electrical stimulation applied to the lower limbs has been reported to provide some benefit by achieving muscular contraction and improving venous flow. Local pain, a common symptom of DVT, is often absent because of sensory deficits. Thus, a regular schedule of visual inspection for local signs of DVT (e.g., swelling) is important. Testing of people at high risk for DVT includes plethysmography and duplex ultrasonography.

Dependent edema is also a common problem in people with SCI. The development of edema is related to decreased peripheral vascular resistance, decreased muscle tone in the paralyzed limbs, and immobility that causes increased venous pressure and abnormal pooling of blood in the abdomen, lower limbs, and upper extremities. Positioning to minimize gravitational forces or by using compression devices (e.g., support stockings, binders) that encourage venous return usually relieves edema in the dependent body parts.

Skin Integrity. The entire surface of the skin is innervated by cranial or spinal nerves organized into dermatomes that show cutaneous distribution. The CNS and autonomic nervous system also play a vital role in skin function. The sympathetic nervous system, through control of vasomotor and sweat gland activity, influences the health of the skin by providing adequate circulation, excretion of body fluids, and temperature regulation. The lack of sensory warning mechanisms and voluntary motor ability below the level of injury, coupled with circulatory changes, places the spinal cord–injured person at major risk for disruption of skin integrity. Significant factors associated with disruption of skin integrity are pressure, shearing forces, and localized trauma and irritation. Relieving pressure, allowing adequate circulation to the skin, and skin inspection are primary ways of maintaining skin integrity. Of all the complications after SCI, skin breakdown is the most preventable.

Future Directions in Repair of the Injured Spinal Cord

Currently, strategies for repairing the injured spinal cord focus on promoting the regrowth of interrupted nerve fiber tracts, using nerve growth-stimulating factors or molecules that suppress inhibitors of neuronal extension; bridging spinal cord lesions with scaffolds that are impregnated with nerve growth factors, which promote axon growth and reduce the barriers caused by scar tissue; repairing damaged myelin and restoring nerve fiber conductivity in the lesion area; and enhancing CNS plasticity by promoting compensatory growth of spared, intact nerve fibers above and below the level of injury. Although these strategies may not allow for complete repair of the spinal cord so as to recreate what was present before the injury, even small successes may be useful for someone with SCI.

IN SUMMARY

UMN lesions are those involving neurons completely contained in the CNS. ALS is a progressive and devastating neurologic disorder that selectively affects motor function. It affects LMNs in the spinal cord as well as UMN lesions in the brain stem and cerebral cortex. MS is a slowly progressive demyelinating disease of the CNS. The most common symptoms are paresthesias, optic neuritis, and motor weakness. The disease is usually characterized by exacerbations and remissions. Initially, near-normal function returns between exacerbations.

SCI is a disabling neurologic condition most commonly caused by motor vehicle accidents, falls, and sports injuries. Dysfunctions of the nervous system after SCI comprise various degrees of sensorimotor loss and altered reflex activity based on the level of injury and extent of cord damage. Depending on the level of injury, the physical problems of SCI include spinal shock; ventilation and communication problems; autonomic nervous system dysfunction that predisposes to the vasovagal response, autonomic hyperreflexia, impaired body temperature regulation, and postural hypotension; impaired muscle pump and venous innervation leading to edema of dependent areas of the body and risk for DVT; altered sensorimotor integrity that contributes to uncontrolled muscle spasms, altered pain responses, and threats to skin integrity; alterations in bowel and bladder elimination; and impaired sexual function.
REVIEW EXERCISES

1. A 32-year-old woman presents with complaints of drooping eyelids, difficulty chewing and swallowing, and weakness of her arms and legs that is less severe in the morning but becomes worse as the day progresses. She complains that climbing stairs and lifting objects are becoming increasingly difficult. Clinical examination confirms weakness of the eyelid and jaw muscles. She is told that she may have myasthenia gravis and is scheduled for a blood test to assess for antibodies.
   A. Explain the pathogenesis of this woman’s symptoms as it relates to myasthenia gravis.
   B. Explain how information from the antibody blood test can be used to assist in the diagnosis of the disorder.
   C. Explain the rationale for avoiding the use of the aminoglycoside antibiotics for treatment of infections in this woman.

2. A 66-year-old man complains of right-hand tremor at rest that interferes with his various graphic design creations. He also complains of dragging his left leg when walking, being unsteady when turning, and a stooped over position of the trunk indicating a gait disturbance. Upon examination he is found to also have weakness of the eyelid and jaw muscles.

   A. How would you go about helping him to outline the role of the cerebellum and basal ganglia in performing the motor movements associated with these maneuvers?

3. A 20-year-old man suffered an SCI at the C2 to C3 level as the result of a motorcycle accident.
   A. Explain the effects of this man’s injury on ventilation and communication; sensorimotor function; autonomic nervous system function; bowel, bladder, and sexual functions; and temperature regulation.
   B. Autonomic dysreflexia, which is a threat to people with SCI at T6 or above, is manifested by hypertension, often to extreme levels, and bradycardia; constriction of skin vessels below the level of injury; and severe headache and nasal stuffiness. Explain the origin of the elevated blood pressure and bradycardia. The condition does not occur until after shock has resolved and usually occurs only in people with injuries at T6 and above. Explain.

The brain is susceptible to injury by trauma, ischemia, tumors, degenerative processes, and metabolic derangements. Brain injuries can be categorized as traumatic (i.e., epidural hematoma, subdural hematoma, concussion, contusion, or diffuse axonal injury) or nontraumatic (i.e., stroke, infection, tumor, or seizure). Brain injuries can cause a change in level of consciousness and alterations in cognition, motor, and sensory function. Brain damage can result from the effects of ischemia, excitatory amino acids, edema, and increased intracranial pressure.
autoregulatory mechanisms that ensure its blood supply. Nonetheless, the brain remains remarkably vulnerable to injury by trauma, ischemia, tumors, degenerative processes, and metabolic derangements.

**Manifestations of Brain Injury**

Brain injury, whether due to trauma, stroke, or other pathologic processes, is manifested by changes in the level of consciousness and alterations in cognitive, motor, and sensory function. Focal brain injury causes focal neurologic deficits that may, or may not, alter consciousness. Global brain injury nearly always results in altered levels of consciousness, ranging from inattention to stupor or coma. Severe injury that seriously compromises brain function may result in brain death.

The cerebral hemispheres are the most susceptible to damage, and the most frequent sign of brain dysfunction is an altered level of consciousness and change in behavior. As the brain structures in the diencephalon, midbrain, pons, and medulla are sequentially affected, additional signs related to pupillary and eye movement reflexes, motor function, and respiration become evident (Table 20.1). Hemodynamic and respiratory instability are the last signs to occur because their regulatory centers are located low in the medulla.

With progressive neurologic deterioration, the person’s neurologic capabilities appear to deteriorate in a stepwise fashion. Similarly, as neurologic function returns, there appears to be a stepwise progress to higher levels of consciousness. Deterioration of brain function from supratentorial lesions tends to follow a rostral-to-caudal stepwise progression, which is observed as the brain initially compensates for injury and subsequently decompensates with loss of autoregulation and cerebral perfusion. Infratentorial (brain stem) lesions may lead to an early, sometimes abrupt disturbance in consciousness without any orderly rostrocaudal progression of neurologic signs.

### Altered Levels of Consciousness

All forms of brain injury and disease can lead to altered levels of consciousness. Consciousness is the state of awareness of self and the environment and of being able to orient to new stimuli. It is divided into two components:

1. Arousal and wakefulness
2. Content and cognition

The content and cognition aspects of consciousness are determined by a functioning cerebral cortex. Arousal and wakefulness require the concurrent functioning of both cerebral hemispheres and an intact reticular activating system (RAS) in the brain stem.

### Anatomic and Physiologic Basis of Consciousness.

The reticular formation is a diffuse, primitive system of interlacing nerve cells and fibers in the brain stem that receive input from multiple sensory pathways (Fig. 20.1). Anatomically, the reticular formation constitutes the central core of the brain stem, extending from the medulla through the pons to the midbrain, that is continuous caudally with the spinal cord and rostrally with the subthalamus, the hypothalamus, and the thalamus. Fibers from the RAS also project to the autonomic nervous system and motor systems. The hypothalamus plays a predominant role in maintaining homeostasis through integration of somatic, visceral, and endocrine functions. Inputs from the reticular formation, vestibulospinal projections, and other motor systems are integrated to provide a continuously adapting background of muscle tone and posture to facilitate voluntary motor actions. Reticular formation neurons that function in regulation of cardiovascular, respiratory, and other visceral functions are intermingled with those that maintain other reticular formation functions.

Ascending fibers of the reticular formation, known as the ascending RAS, transmit activating information to all parts of the cerebral cortex. The flow of information in the ascending

Chapter 20  Disorders of Brain Function

RAS activates the hypothalamic and limbic structures that regulate emotional and behavioral responses such as those that occur in response to pain and loud noises, and they exert facilitatory effects on cortical neurons. Without cortical activation, a person is less reactive to environmental stimuli, and the level of consciousness is reduced.

The pathways for the ascending RAS travel from the medulla through the midbrain, such that lesions of the brain stem can interrupt RAS activity, leading to altered levels of consciousness and coma. Any deficit in level of consciousness, from mild confusion to stupor or coma, indicates either direct injury to the RAS or to both cerebral hemispheres concurrently. For example, consciousness may decline owing to severe systemic metabolic derangements that affect both hemispheres or from head trauma causing shear injuries to white matter of both the RAS and the cerebral hemispheres. Brain injuries that affect a hemisphere unilaterally and also spare the RAS, such as cerebral infarction, usually do not cause impaired consciousness.

Levels of Consciousness. Levels of consciousness reflect awareness and response to the environment. A fully conscious person is totally aware of her or his surroundings and able to react to stimuli in the environment. Levels of consciousness exist on a continuum that includes consciousness, confusion, lethargy, obtundation, stupor, and coma (Table 20.2).

The earliest signs of diminution in level of consciousness are inattention, mild confusion, disorientation, and blunted responsiveness. With further deterioration, the delirious person becomes markedly inattentive and variably lethargic or agitated. The person may progress to become obtunded and may respond only to vigorous or noxious stimuli.

Because of its simplicity of application, the Glasgow Coma Scale has gained almost universal acceptance as a method for assessing the level of consciousness in people with brain injury (Table 20.3). Numbered scores are given to responses of eye opening, verbal utterances, and motor responses. The total score is the sum of the best response in each category.

be used to determine whether the brain stem centers for eye movement are intact (Fig. 20.2).

If the oculocephalic reflex is inconclusive, and if there are no contraindications, the oculovestibular reflex (i.e., cold caloric test, in which cold water is instilled into the ear canal) may be used to elicit nystagmus.

**Abnormal Flexion and Extension Posturing.** With the early onset of unconsciousness, there is some combative and purposeful movement in response to pain. As coma progresses, noxious stimuli can initiate rigidity and abnormal postures if the motor tracts are interrupted at specific levels. These abnormal postures are classified as decorticate and decerebrate. Decorticate (flexion) posturing is characterized by flexion of the arms, wrists, and fingers, with abduction of the upper extremities, internal rotation, and plantar flexion of the lower extremities (see Fig. 20.6A). Decortic posturing results from lesions of the cerebral hemisphere or internal capsule. Decerebrate (extensor) posturing is characterized by rigidity of the arms with palms of the hands turned away from the body and with stiffly extended legs and plantar flexion of the feet. This response occurs with rostral-to-caudal deterioration, when lesions of the diencephalon extend to involve the midbrain and upper brain stem. Both decerebrate and decorticate posturing are poor prognostic signs.

**KEY POINTS**

**BRAIN INJURY AND LEVELS OF CONSCIOUSNESS**

- Consciousness is a global function that depends on a diffuse neural network that includes both cerebral hemispheres and activity of the RAS.
- Impaired consciousness implies diffuse brain injury to both cerebral hemispheres simultaneously or the RAS at any level (medulla through thalamus).
- In contrast, local brain injury causes focal neurologic deficit but does not disrupt consciousness.

**Other Manifestations of Deteriorating Brain Function**

Additional elements in the initial neurologic evaluation of a person with brain injury include checking for abnormalities in the size of the pupils and their reaction to light, evidence of abnormal flexion or extension posturing, and altered patterns of respiration.

**Pupillary Reflexes and Eye Movements.** Although the pupils may initially respond briskly to light, they become nonreactive and dilated as brain function deteriorates. A bilateral loss of the pupillary light response is indicative of lesions of the brain stem. A unilateral loss of the pupillary light response may be due to a lesion of the optic or oculomotor pathways. The oculocephalic reflex (doll’s-head eye movement) can
Respiratory Responses. Early respiratory changes include yawning and sighing, with progression to Cheyne-Stokes breathing. With progression of injury continuing to the midbrain, respirations change to central neurogenic hyperventilation, in which the frequency of respirations may exceed 40 breaths per minute because of uninhibited stimulation of inspiratory and expiratory centers. With medullary involvement, respirations become ataxic (i.e., totally uncoordinated and irregular). Apnea may occur because of a lack of responsiveness to carbon dioxide stimulation. Complete ventilatory assistance is often required at this point.

Brain Death

Brain death is defined as the irreversible loss of function of the brain, including the brain stem. Irreversibility implies that brain death cannot be reversed. Some conditions such as drug and metabolic intoxication can cause cessation of brain functions that is completely reversible, even when they produce clinical cessation of brain functions and electroencephalographic (EEG) silence. This needs to be excluded before declaring a person brain dead.

With advances in scientific knowledge and technology that have provided the means for artificially maintaining ventilatory and circulatory function, the definition of death has had to be continually reexamined. In 2010, the Quality Standards Subcommittee of the American Academy of Neurology published the evidence-based guideline update for clinical parameters for determining brain death and procedures for testing persons older than 18 years of age. According to these parameters, “brain death is the absence of clinical brain function when the proximate cause is known and demonstrably irreversible.” This update found that complex—spontaneous motor movements and false-positive triggering of the ventilator may occur in people who are brain dead. They also found insufficient evidence to determine the minimally acceptable observation period to ensure that neurologic functions have ceased irreversibly. It is safe to determine apnea with the apneic oxygenation diffusion, but there is insufficient evidence to determine the comparative safety of techniques used for apnea testing. The newer ancillary tests also had insufficient evidence to determine cessation of brain function. Longer periods of observation of absent brain activity are required if the patient is a child and in cases of drug overdose (e.g., barbiturates, other central nervous system [CNS] depressants), drug toxicity (e.g., neuromuscular blocking drugs, aminoglycoside antibiotics) and neuromuscular diseases such as myasthenia gravis, hypothermia, and shock. Medical circumstances may require the use of confirmatory tests.

Medical documentation should include cause and irreversibility of the condition, absence of brain stem reflexes and motor responses to pain, absence of respiration with a pressure of carbon dioxide (PCO₂) of 60 mm Hg or more, and the justification for use of confirmatory tests and their results. Apnea is confirmed after ventilation with pure oxygen 10 minutes before withdrawal from the ventilator, followed by passive flow of oxygen. This method allows the PCO₂ to rise to 60 mm Hg after a 10-minute period of apnea, without hazardously lowering the oxygen content of the blood. If respiratory reflexes are intact, the hypercapnia that develops should stimulate ventilatory effort within 30 seconds. Spontaneous breathing efforts indicate that the brain stem is functioning. Confirmatory tests of brain death include conventional angiography (i.e., no intracerebral filling at the level of the carotid bifurcation or circle of Willis), transcranial Doppler ultrasonography, technetium-99m hexamethylpropyleneamine oxime brain scan (i.e., no uptake of isotope in brain parenchyma), somatosensory evoked potentials, and EEG. In the United States, EEG testing is often used to establish brain death. EEG testing should reveal no electrical activity during at least 30 minutes of recording that adheres to the minimal technical criteria for EEG recording in suspected brain death as adopted by the American Electroencephalographic Society (including 16-channel EEG instruments).

Persistent Vegetative State

Advances in the care of brain-injured persons during the past several decades have resulted in survival of many persons who previously would have died. Unfortunately, most persons in prolonged coma who survive evolve to what often is called the persistent vegetative state. The vegetative state is characterized by loss of all cognitive functions and the unawareness of self and surroundings. Reflex and vegetative functions remain, including sleep–wake cycles. These people have spontaneous eye opening without concurrent awareness, often confusing hopeful families. People in the vegetative state require nonoral feeding and full nursing care.

The criteria for diagnosis of vegetative state include the absence of awareness of self and environment and an inability to interact with others; the absence of sustained or reproducible voluntary behavioral responses; lack of language comprehension; sufficiently preserved hypothalamic and brain stem function to maintain life; bowel and bladder incontinence; and variably preserved cranial nerve (e.g., pupillary, gag) and spinal cord reflexes. The diagnosis of persistent vegetative state requires that the condition has continued for at least 1 month. The minimally conscious state has been defined as a state of arousal similar to persistent vegetative state, but with the distinction of the objective presence of some awareness on the part of the patient.

Mechanisms of Brain Injury

Injury to brain tissue can result from a number of conditions, including trauma, tumors, stroke, metabolic derangements, and degenerative disorders. Brain damage resulting from these disorders involves several common pathways, including the effects of ischemia, excitatory amino acid injury, cerebral edema, and injury due to increased intracranial pressure (ICP). In many cases, the mechanisms of injury are interrelated.
Hypoxic and Ischemic Injury

The energy requirements of the brain are provided mainly by adenosine triphosphate (ATP). The ability of the cerebral circulation to deliver oxygen in sufficiently high concentrations to facilitate metabolism of glucose and generate ATP is essential to brain function. Although the brain makes up only 2% of the body’s weight, it receives 15% of the resting cardiac output and accounts for 20% of the oxygen consumption.8,9 Thus, deprivation of oxygen or blood flow can have a deleterious effect on brain structures.

By definition, hypoxia denotes a deprivation of oxygen with maintained blood flow (perfusion), whereas ischemia is a situation of greatly reduced or interrupted blood flow. The brain tends to have different sensitivities to the two conditions. Whereas hypoxia interferes with the delivery of oxygen, ischemia interferes with delivery of oxygen and glucose as well as the removal of metabolic wastes. Hypoxia usually is seen in conditions such as exposure to reduced atmospheric pressure, carbon monoxide poisoning, severe anemia, and failure to oxygenate the blood. Because hypoxia indicates decreased oxygen levels in all brain tissue, it produces a generalized depressant effect on the brain. Neurons are capable of substantial anaerobic metabolism and are fairly tolerant of pure hypoxia. It commonly produces euphoria, listlessness, drowsiness, and impaired problem solving. Unconsciousness and seizures may occur when hypoxia is sudden and severe. However, the effects of severe hypoxia (i.e., anoxia) on brain function seldom are seen because the condition rapidly leads to cardiac arrest and ischemia.

Cerebral ischemia can be focal, as in stroke, or global, as in cardiac arrest. In global ischemia, the blood flow to the entire brain is compromised. In contrast, during focal ischemia, only a region of the brain is underperfused, as in ischemic stroke. Collateral circulation provides blood flow to uninvolved brain areas during focal ischemia. The collateral perfusion may even provide sufficient substrates to the borders of the focal ischemic region to maintain a low level of metabolic activity, thereby preserving membrane integrity. At the same time, interruption in delivery of glucose under these anaerobic conditions may result in additional lactic acid production and depletion of ATP stores.8

Global Ischemia. Global ischemia occurs when blood flow is inadequate to meet the metabolic needs of the entire brain. The result is a spectrum of neurologic disorders reflecting global brain dysfunction. Unconsciousness occurs within seconds of severe global ischemia, such as that resulting from complete cessation of blood flow, as in cardiac arrest, or with marked decrease in blood flow, as in serious cardiac arrhythmias. If cerebral circulation is restored immediately, consciousness is regained quickly. However, if blood flow is not promptly restored, severe pathologic changes take place. Energy sources, glucose and glycogen, are exhausted in 2 to 4 minutes, and cellular ATP stores are depleted in 4 to 5 minutes. Approximately 50% to 75% of the total energy requirement of neuronal tissue is spent on mechanisms for maintenance of ionic gradients across the cell membrane (e.g., sodium–potassium pump), resulting in fluxes of sodium, potassium, and calcium ions.10 Excessive influx of sodium results in neuronal depolarization and depensation, which may result in the release of intracellular and nuclear enzymes that cause cell destruction. When ischemia is sufficiently severe or prolonged, infarction or death of all the cellular elements of the brain occurs. Even if blood flow is restored, if ischemic thresholds for injury were exceeded, then permanent cell death ensues. Furthermore, reperfusion of injured tissues can lead to secondary brain injury through the delivery of inflammatory cells and toxic by-products, including excitatory amino acids. Such reperfusion injury compounds the initial ischemic damage.

The pattern of global ischemia reflects the anatomic arrangement of the cerebral vessels and the sensitivity of various brain tissues to oxygen deprivation11 (Fig. 20.3). Selective neuronal sensitivity to a lack of oxygen is most apparent in the Purkinje cells of the cerebellum and neurons in the Sommer sector of the hippocampus, where cell death occurs earliest after global ischemia. The anatomic arrangement of the cerebral blood vessels predisposes to two types of injury: watershed infarcts and laminar necrosis.

Watershed infarcts are concentrated in anatomically vulnerable border zones between the overlapping territories supplied by the major cerebral arteries, notably the middle, anterior, and posterior cerebral arteries. The overlapping territory at the distal ends of these vessels forms extremely vulnerable areas in terms of global ischemia, called watershed zones. During events such as severe hypotension, these distal territories undergo a profound lowering of blood flow, predisposing to focal ischemia and infarction of brain tissues. Therefore,
global ischemia can result in focal infarcts that occur in the border zones between major vascular territories. This is in contrast to primarily focal ischemia in which the pattern of infarction is within a vascular territory. Laminar necrosis refers to short, serpiginous segments of necrosis that occur within and parallel to the cerebral cortex, in areas supplied by the penetrating arteries. The gray matter of the cerebral cortex receives its major blood supply through short penetrating arteries that emerge at right angles from larger vessels in the pia mater and then form a cascade as they repeatedly branch, forming a rich capillary network. An abrupt loss of arterial blood pressure markedly diminishes flow through these capillary channels. Because the third cortical layer is most sensitive to ischemia, the necrosis that develops is laminar and is most severe in this deep layer of the cortex.

The neurologic deficits that result from global ischemic injury vary widely. If the period of nonflow or low flow is minimal, the neurologic damage usually is minimal to nonexistent. When the period is extensive or resuscitation is lengthy, the early neurologic clinical picture is that of coma, fixed, dilated pupils, and abnormal motor posturing. If the victim survives, there may be gradual improvement in neurologic status, although permanent cognitive and focal deficits usually persist and can prevent a return to preischemic levels of functioning.

An exception to this time frame is the circumstance of cold-water drowning in which the person, especially a child, is submerged in cold water for longer than 10 minutes. Hypothermia develops and reduces the cerebral metabolic requirements for oxygen, minimizes intracellular acidosis, and lessens the effects of excitotoxic by-products. In this case, recovery can be rapid and remarkable, and resuscitation efforts should not be discontinued precipitously.

Treatment of global cerebral ischemia varies with the underlying cause (e.g., cardiac arrest, hanging, asthma attack). General goals common to all causes are aimed at providing oxygen to the injured brain and decreasing the metabolic needs of brain tissue during the nonflow state. Hemodynamic support aimed at restoring systemic and cerebral perfusion is required. Respiratory support including mechanical ventilation and supplemental oxygen may be indicated. Methods that decrease brain temperature as a means of decreasing brain metabolism, as in cold-water drowning, are effective in certain patients after cardiac arrest. Normovolemic hemodilution may be used to overcome sludging of cerebral blood flow during reperfusion. Because both hypoglycemia and hyperglycemia adversely affect the outcome in people with global ischemia, control of blood glucose around the level of 140 mg/dL is appropriate.

**Excitotoxic Brain Injury**

In many neurologic disorders, injury to neurons may be caused by various mediators, including excitatory amino acids, catecholamines, nitric oxide, free radicals, inflammatory cells, apoptosis, and intracellular proteases. The neurologic conditions involved in excitotoxic injury range from acute insults such as stroke, hypoglycemic injury, and trauma to chronic degenerative disorders such as Huntington disease and possibly Alzheimer dementia. The term excitotoxicity has been coined for the final common pathway for neuronal cell injury and death triggered by excessive activity of the excitatory neurotransmitters and their receptor-mediated effects.

Glutamate is the principal excitatory neurotransmitter in the brain, and its interaction with specific receptors is responsible for many higher-order functions, including memory, cognition, movement, and sensation. Many of the actions of glutamate are coupled with receptor-operated ion channels. One subtype in particular, the glutamate N-methyl-D-aspartate (NMDA) receptor, has been implicated in causing CNS injury. This subtype of glutamate receptor opens a large-diameter calcium channel that permits calcium and sodium ions to enter the cell and allows potassium ions to exit, resulting in prolonged (seconds) action potentials. The intracellular concentration of glutamate is approximately 16 times that of the extracellular concentration. Normally, extracellular concentrations of glutamate are tightly regulated, with excess amounts removed and actively transported into astrocytes and neurons.

During prolonged ischemia, the glutamate transport mechanisms become immobilized, causing extracellular glutamate to accumulate. In addition, intracellular glutamate is released from the damaged cells. This glutamate excess then drives the uncontrolled opening of NMDA receptor-operated channels, producing an increase in intracellular calcium. Excess intracellular calcium leads to a series of calcium-mediated processes called the calcium cascade (Fig. 20.4), including the release of intracellular enzymes that cause protein breakdown, free radical formation, lipid peroxidation, fragmentation of deoxyribonucleic acid (DNA), mitochondrial injury, nuclear breakdown, and eventually cell death.

The effects of acute glutamate toxicity may be reversible if the excess glutamate can be removed or if its effects can be blocked before the full cascade of events progresses. Drugs called neuroprotectants are being developed to interfere with the calcium cascade and thus reduce brain cell injury. These pharmacologic strategies may protect viable brain cells from irreversible damage in the setting of excitotoxicity. Pharmacologic strategies being explored include those that inhibit the synthesis or release of excitatory amino acid transmitters; block the NMDA receptors; stabilize the membrane potential to prevent initiation of the calcium cascade using lidocaine and certain barbiturates; and specifically block certain intracellular proteases, endonucleases, and lipases that are known to be cytotoxic. The drug riluzole, which acts presynaptically to inhibit glutamate release, currently is being used in the treatment of amyotrophic lateral sclerosis (see Chapter 19). In the setting of ischemic stroke, multiple mechanisms of pharmacologic action, including NMDA receptor blockade, nitric oxide manipulation, inflammatory suppression, and potassium channel opening, are being studied.

CNS neurons can be divided into two major categories: macroneurons and microneurons. Macroneurons are
The microneurons of the cerebral cortex and hippocampus are particularly vulnerable to excessive stimulation of the glutamate NMDA receptors and the neurotoxic effects of increased intracellular calcium levels. Because of their increased vulnerability, many of the small interneurons that make up essential parts of the complex control and memory functions of the brain are selectively damaged, even if the remainder of the brain survives the insult. This pattern may account for the long-term effects of brain insult, which frequently include subtle reductions in cognitive and memory functions.

Increased Intracranial Pressure

The brain is enclosed in the rigid confines of the skull, or cranium, making it particularly susceptible to increases in ICP. Increased ICP is a common pathway for brain injury from different types of insults and agents. Excessive ICP can obstruct cerebral blood flow, destroy brain cells, displace brain tissue (as in herniation), and otherwise damage delicate brain structures (Table 20.4).

The cranial cavity contains blood (approximately 10%), brain tissue (approximately 80%), and CSF (approximately 10%) in the rigid confines of a nonexpandable skull.2 Each of these three volumes contributes to the ICP, which normally is maintained within a range of 0 to 15 mm Hg when measured in the lateral ventricles. The volumes of each of these components can vary slightly without causing marked changes in ICP. This is because small increases in the volume of one component can be compensated for by a decrease in the volume of one or both of the other two components. This dynamic equilibrium is called the Monro-Kellie hypothesis.2 Abnormal variation in intracranial volume with subsequent changes in ICP can be caused by a volume change in any of the three intracranial components. For example, an increase in tissue volume can result from a brain tumor, brain edema, or bleeding into brain tissue. An increase in blood volume develops when there is vasodilation of cerebral vessels or obstruction of venous outflow. Excess production, decreased absorption, or obstructed circulation of CSF affords the potential for an increase in the CSF component. The Monro-Kellie hypothesis explains the reciprocal compensation that occurs among the three intracranial compartments (blood, brain tissue, and CSF).2

Of the three intracranial volumes, tissue volume is relatively restricted in its ability to undergo change. CSF...
and blood volume are best able to compensate for changes in ICP. Initial increases in ICP are buffered by a translocation of CSF to the spinal subarachnoid space and increased reabsorption of CSF. The compensatory ability of the blood compartment is limited by the small amount of blood that is in the cerebral circulation. The cerebral blood vessels contain less than 10% of the intracranial volume, most of which is contained in the low-pressure venous system. As the volume-buffering capacity of this compartment becomes exhausted, venous pressure increases, and cerebral blood volume and ICP rise. Also, cerebral blood flow is highly controlled by autoregulatory mechanisms, which affect its compensatory capacity. Conditions such as ischemia and an elevated partial PCO₂ in the blood produce a compensatory vasodilation of the cerebral blood vessels. A decrease in ICP is the Cushing triad (reflex), which is triggered by ischemia of the vasomotor center in the brain stem. Neurons in the vasomotor center respond directly to ischemia by producing a marked increase in MAP in an attempt to increase CPP, accompanied by a widening of the pulse pressure and reflex slowing of the heart rate. These three signs (i.e., hypertension, bradycardia, and widened pulse pressure), called the Cushing reflex, are important but late indicators of increased ICP.17

**Brain Herniation**

The brain is protected by the nonexpandable skull and supporting septa, the falx cerebri and the tentorium cerebelli, that divide the intracranial cavity into fossae or compartments that normally protect against excessive movement. The falx cerebri is a sickle-shaped septum that separates the two hemispheres. The tentorium cerebelli divides the cranial cavity into anterior and posterior fossae. This inflexible dural sheath extends posteriorly from the bony petrous ridges and anterior to the clinoid process, sloping downward and outward from its medial edge to attach laterally to the occipital bone. Extending posteriorly into the center of the tentorium is a large semicircular opening called the incisura or tentorial notch. The temporal lobe rests on the tentorial incisura, and the midbrain occupies the anterior portion of the tentorial notch. The cerebellum is closely opposed to the dorum of the midbrain and fills the posterior part of the notch. Other important anatomic associations exist among the anterior cerebral, internal carotid, posterior communicating, and posterior and superior cerebellar arteries and the incisura. The oculomotor nerve (cranial nerve III) emerges from the mediolateral surface of each peduncle just caudal to the tentorium.

Brain herniation represents a displacement of brain tissue under the falx cerebri or through the tentorial notch or incisura of the tentorium cerebelli (see Fig. 20.5). It occurs when an elevated ICP in one brain compartment causes displacement of the cerebral tissue toward an area of lower ICP. The different types of herniation syndromes are based on the area of the brain that has herniated and the structure under which it has been pushed. They commonly are divided into two broad categories, supratentorial and infratentorial, based on whether they are located above or below the tentorium.

**Supratentorial Herniations.** Three major patterns of supratentorial herniation were described by Plum and Posner1 in their classic work: cingulate, central transtentorial, and uncal

Understanding Intracranial Pressure

The ICP is the pressure within the intracranial cavity. It is determined by (1) the pressure–volume relationships among the brain tissue, CSF, and blood in the intracranial cavity; (2) the Monro-Kellie hypothesis, which relates to reciprocal changes among the intracranial volumes; and (3) the compliance of the brain and its ability to buffer changes in intracranial volume.

Intracranial Volumes and Pressure

The ICP represents the pressure exerted by the essentially incompressible tissue and fluid volumes of the three compartments contained within the rigid confines of the skull—the brain tissue and interstitial fluid (80%), the blood (10%), and the CSF (10%).

Monro-Kellie Hypothesis

Normally, a reciprocal relationship exists among the three intracranial volumes such that the ICP is maintained within normal limits. Because these volumes are practically incompressible, a change in one component must be balanced by an almost equal and opposite effect in one or both of the remaining components. This is known as the Monro-Kellie hypothesis.

Of the three intracranial volumes, the fluid in the CSF compartment is the most easily displaced. The CSF (A) can be displaced from the ventricles and cerebral subarachnoid space to the spinal subarachnoid space, and it can also undergo increased absorption or decreased production. Because most of the blood in the cranial cavity is contained in the low-pressure venous system, venous compression (B) serves as a means of displacing blood volume.
Compliance and the Volume–Pressure Curve

Compliance, which refers to the ease with which a substance can be compressed or deformed, is a measure of the brain’s ability to maintain its ICP during changes in intracranial volume. Compliance ($C$) represents the ratio of change ($\Delta$) in volume ($V$) to change in pressure ($P$): $C = \frac{\Delta V}{\Delta P}$.

The dynamic effects of changes in intracranial volume and compliance on ICP can be illustrated on a graph with the volume represented on the horizontal axis and ICP on the vertical axis. The shape of the curve demonstrates the effect on ICP of adding volume to the intracranial cavity. From points A to B, the compensatory mechanisms are adequate, compliance is high, and the ICP remains relatively constant as volume is added to the intracranial cavity. At point B, the ICP is relatively normal, but the compensatory mechanisms have reached their limits, compliance is decreased, and ICP begins to rise with each change in volume. From points C to D, the compensatory mechanisms have been exceeded, and ICP rises significantly with each increase in volume as compliance is lost.

Compliance, which refers to the ease with which a substance can be compressed or deformed, is a measure of the brain’s ability to maintain its ICP during changes in intracranial volume. Compliance ($C$) represents the ratio of change ($\Delta$) in volume ($V$) to change in pressure ($P$): $C = \frac{\Delta V}{\Delta P}$.

The shape of the curve demonstrates the effect on ICP of adding volume to the intracranial cavity. From points A to B, the compensatory mechanisms are adequate, compliance is high, and the ICP remains relatively constant as volume is added to the intracranial cavity. At point B, the ICP is relatively normal, but the compensatory mechanisms have reached their limits, compliance is decreased, and ICP begins to rise with each change in volume. From points C to D, the compensatory mechanisms have been exceeded, and ICP rises significantly with each increase in volume as compliance is lost.

Central transtentorial herniations involve the downward displacement of the cerebral hemispheres, basal ganglia, diencephalon, and midbrain through the tentorial incisura. The diencephalon may be compressed tightly against the midbrain with such force that edema and hemorrhage result. It may or may not be associated with uncal or lateral herniation. In the early diencephalic stage, there is clouding of consciousness, bilaterally small pupils (approximately 2 mm in diameter) with a full range of constriction, and motor responses to pain that are purposeful or semipurposeful (localizing) and often asymmetric. The clouding of consciousness, which is often a first sign of central herniations, is caused by pressure on the RAS in the upper midbrain, which is responsible for wakefulness. As the herniation progresses to the late diencephalic stage, painful stimulation results in decorticate posturing, which may be asymmetric.

(see Fig. 20.6A), and there is waxing and waning of respirations with periods of apnea (Cheyne-Stokes respirations). With midbrain involvement, the pupils are fixed and midsize (approximately 5 mm in diameter), and reflex adduction of the eyes is impaired; pain elicits decerebrate posturing (Fig. 20.6B); and respirations change from Cheyne-Stokes to neurogenic hyperventilation, in which the frequency may exceed 40 breaths per minute because of uninhibited stimulation of the inspiratory and expiratory centers. Progression to involve the lower pons and upper medulla produces fixed, midpoint (3- to 5-mm) pupils with loss of reflex abduction and adduction of the eyes, and absence of motor responses or only leg flexion on painful stimuli. Once the area of herniation has progressed beyond the diencephalon and into the midbrain and brain stem, the process is generally irreversible and the prognosis poor.2

Uncal herniation occurs when a lateral mass pushes the brain tissue centrally and forces the medial aspect of the temporal lobe, which contains the uncus and hippocampal gyrus, under the edge of the tentorial incisura, into the posterior fossa. As a result, the diencephalon and midbrain are compressed and displaced laterally to the opposite side of the tentorium. Cranial nerve III (oculomotor nerve) and the posterior cerebral artery frequently are caught between the uncus and the tentorium. The oculomotor nerve controls pupillary constriction; entrapment of this nerve results in ipsilateral pupillary dilation, which usually is an early sign of uncal herniation. Consciousness may be unimpaired because the RAS has not yet been affected. However, after any signs of herniation or brain stem compression appear, deterioration may proceed rapidly—making it important to recognize the distinguishing early features of uncal herniations.

As uncal herniations progress, there are changes in motor strength and coordination of voluntary movements because of compression of the descending motor pathways. It is not unusual for initial changes in motor function to occur ipsilateral to the side of the brain damage because of compression of the contralateral cerebral peduncles. This may result in a false localizing sign of hemiparesis on the same side as cranial nerve III, rather than on the opposite side, which would be the case if a singular lesion in the midbrain were the cause. As the condition progresses, bilateral positive Babinski responses and respiratory changes (e.g., Cheyne-Stokes respirations, ataxic patterns) occur. Decorticate and decerebrate posturing may develop, followed by dilated, fixed pupils, flaccidity, and respiratory arrest.

Infratentorial Herniation. Infratentorial herniation results from increased pressure in the infratentorial compartment. It often progress rapidly and can cause death because it is likely to involve the lower brain stem centers that control vital cardiopulmonary functions. Herniation may occur superiorly (upward) through the tentorial incisura or inferiorly (downward) through the foramen magnum.

Upward displacement of brain tissue can cause blockage of the aqueduct of Sylvius and lead to hydrocephalus and coma. Downward displacement of the midbrain through the tentorial notch or the cerebellar tonsils through the foramen magnum can interfere with medullary functioning and cause cardiac or respiratory arrest. In cases of preexisting ICP elevations, herniation may occur when the pressure is released from below, such as in a lumbar puncture. If the CSF pathway is blocked and fluid cannot leave the ventricles, the volume expands, and fluid is displaced downward through the tentorial notch. The expanding volume causes all function at a given level to cease as destruction progresses in a rostral-to-caudal direction. The result of this displacement is brain stem ischemia and hemorrhage extending from the diencephalon to the pons. If the lesion expands rapidly, displacement and obstruction occur quickly, leading to irreversible infarction and hemorrhage.

Cerebral Edema
Cerebral edema, or brain swelling, occurs with an increase in water and sodium content causing an increase in brain volume.18 There are two types of brain edema: vasogenic and cytotoxic.3,18 Vasogenic edema occurs when integrity of the blood–brain barrier is disrupted, allowing fluid to escape into the extracellular fluid that surrounds brain cells. Cytotoxic edema involves the actual swelling of brain cells.
Vasogenic Edema. Vasogenic edema occurs with conditions that impair the function of the blood–brain barrier and allow transfer of water and protein from the vascular into the interstitial space. It occurs in conditions such as tumors, prolonged ischemia, hemorrhage, brain injury, and infectious processes (e.g., meningitis). Vasogenic edema occurs primarily in the white matter of the brain, possibly because the white matter is more compliant than the gray matter. Vasogenic edema can displace a cerebral hemisphere and can be responsible for various types of herniation. The functional manifestations of vasogenic edema include focal neurologic deficits, disturbances in consciousness, and severe intracranial hypertension.

Cytotoxic Edema. Cytotoxic edema involves an increase in intracellular fluid. It can result from hypoosmotic states such as water intoxication or severe ischemia that impair the function of the sodium–potassium membrane pump. Ischemia also results in the inadequate removal of anaerobic metabolic end products such as lactic acid, producing extracellular acidosis. If blood flow is reduced to low levels for extended periods or to extremely low levels for a few minutes, cellular edema can cause the cell membrane to rupture, allowing the escape of intracellular contents into the surrounding extracellular fluid. This leads to damage of neighboring cells. The altered osmotic conditions result in water entry and cell swelling. Major changes in cerebral function, such as stupor and coma, occur with cytotoxic edema. The edema associated with ischemia may be severe enough to produce cerebral infarction with necrosis of brain tissue.

Treatment. Although cerebral edema is viewed as a pathologic process, it does not necessarily disrupt brain function unless it increases the ICP. The localized edema surrounding a brain tumor or abscess rapidly begins to reduce signs of brain edema with glucocorticoid therapy, but use of these drugs is not effective for cerebral infarction, intracranial hemorrhage (ICH), subarachnoid hemorrhage (SAH), or traumatic brain injury (TBI) edema. The mechanism of action of the glucocorticoid therapy in the treatment of cerebral edema may be severe enough to produce cerebral infarction. The edema associated with ischemia may be severe enough to produce cerebral infarction with necrosis of brain tissue.

Hydrocephalus

Enlargement of the CSF compartment occurs with hydrocephalus, which is defined as an abnormal increase in CSF volume in any part or all of the ventricular system. The two causes of hydrocephalus are decreased absorption of CSF and obstruction of CSF flow. There are two types of hydrocephalus: noncommunicating and communicating.

Noncommunicating or obstructive hydrocephalus occurs when obstruction in the ventricular system prevents the CSF from reaching the arachnoid villi. CSF flow can be obstructed by congenital malformations, from tumors encroaching on the ventricular system, and by inflammation or hemorrhage. The ependyma (i.e., lining of ventricles and CSF-filled spaces) is especially sensitive to viral infections, particularly during embryonic development; ependymitis is believed to be the cause of congenital aqueductal stenosis.

Communicating hydrocephalus is caused by impaired reabsorption of CSF from the arachnoid villi into the venous system. Decreased absorption can result from a block in the CSF pathway to the arachnoid villi or a failure of the villi to transfer the CSF to the venous system. It can occur if too few villi are formed, if postinfective (meningitis) scarring occludes them, or if the villi become obstructed with fragments of blood or infectious debris. Adenomas of the choroid plexus can cause an overproduction of CSF. This form of hydrocephalus is much less common than that resulting from decreased absorption of CSF.

Similar pathologic patterns occur with noncommunicating and communicating types of hydrocephalus. The cerebral hemispheres become enlarged, and the ventricular system beyond the point of obstruction is dilated. The sulci on the surface of the brain become effaced and shallow, and the white matter is reduced in volume. The presence and extent of the ICP is determined by fluid accumulation and the type of hydrocephalus, the age at onset, and the rapidity and extent of pressure rise. Computed tomographic (CT) and magnetic resonance imaging (MRI) scans are used to diagnose all types of hydrocephalus. The usual treatment is a shunting procedure, which provides an alternative route for return of CSF to the circulation.

Signs and symptoms of hydrocephalus vary greatly, depending on the rapidity of onset. When hydrocephalus develops in utero or before the cranial sutures have fused in infancy, the ventricles expand beyond the point of obstruction, the cranial sutures separate, the head expands, and there is bulging of the fontanelles. Because the skull is able to expand, signs of increased ICP may be absent and intelligence spared. However, seizures are not uncommon, and in severe cases, optic nerve atrophy leads to blindness. Weakness and uncoordinated movement are common. Surgical placement of a shunt allows for diversion of excess CSF fluid, preventing extreme enlargement of the head and neurologic deficits.

In adults, head enlargement does not occur because the cranial sutures are fully fused. Thus, signs and symptoms are likely. Slowly developing hydrocephalus is unlikely to produce an increase in ICP, but it may still produce deficits such as progressive dementia and gait changes, as in normal-pressure hydrocephalus (“pseudotumor cerebri”) in the elderly. In contrast, acute-onset hydrocephalus in adults usually is marked by symptoms of increased ICP, including headache, vomiting, and papilledema or lateral rectus palsy from pressure effects on the cranial nerves. If the obstruction is not relieved, progression to herniation ensues (see previous discussion of herniation). Treatment includes surgical decompression and shunting.
IN SUMMARY

Brain injury is manifested by changes in the level of consciousness and alterations in motor, sensory, and cognitive function. Consciousness is a state of awareness of self and environment. It exists on a continuum from normal wakefulness and sleep to the pathologic states of stupor and coma. In progressive brain injury, the onset of coma may follow a rostral-to-caudal progression with characteristic changes in levels of consciousness, respiratory activity, pupillary and ocuulovestibular reflexes, and muscle tone occurring as the diencephalon through the medulla are affected.

Brain death is defined as the irreversible loss of function of the brain, including that of the brain stem. Clinical examination must disclose at least the absence of responsiveness, brain stem reflexes, and respiratory effort. The vegetative state is characterized by loss of all cognitive functions and the unawareness of self and surroundings, whereas reflex and vegetative functions remain intact.

Many of the agents that cause brain damage do so through common pathways, including hypoxia or ischemia, accumulation of excitatory neurotransmitters, increased ICP, and cerebral edema. Deprivation of oxygen (i.e., hypoxia) or blood flow (i.e., ischemia) can have deleterious effects on the brain structures. Focal ischemia causes localized brain injury, as in stroke. Global ischemia, as in cardiac arrest, occurs when blood flow to the entire brain is inadequate, causing global deficits such as altered mental status.

TRAUMATIC BRAIN INJURY

After completing this section of the chapter, you should be able to meet the following objectives:

- Describe the effects of primary and secondary brain injuries.
- Summarize the different types of hematomas that can occur in the brain.
- Identify focal versus diffuse brain injuries.

The brain is enclosed in the protective confines of the rigid bony skull. Although the skull generally affords protection to the soft tissues of the CNS from external forces, it also imposes risks as a source of injury from internal forces. The bony structures of the internal surface of the skull can induce traumatic and ischemic brain injuries when intracranial tissues increase in volume (swelling or bleeding) or shift (swelling or mechanical trauma). Furthermore, fractures of the skull can compress sections of the nervous system and cause penetrating wounds.

Traumatic brain injury is the leading cause of death and disability among people younger than 24 years of age. The main causes of traumatic brain injury are motor vehicle crashes, falls, and assaults, with the most common cause of fatal head injuries being motor vehicle crashes involving vehicles and pedestrians.

Traumatic brain injuries can involve the scalp, skull, meninges, or brain. Skull fractures can be classified as linear, comminuted, depressed, and basilar. A linear skull fracture is a break in the continuity of bone. A comminuted skull fracture refers to a splintered or multiple fracture line. When bone fragments are embedded into the brain tissue, the fracture is said to be depressed. A fracture of the bones that form the base of the skull is called a basilar skull fracture.

Radiologic examination usually is needed to confirm the presence and extent of a skull fracture. This evaluation is important because of the possible damage to the underlying tissues. The ethmoid cribriform plate, through which the olfactory fibers enter the skull, represents the most fragile portion of the neurocranium and is shattered in basal skull fractures. A frequent complication of basilar skull fractures is leakage of CSF from the nose (rhinorrhea) or ear (otorrhea); this occurs because of the proximity of the base of the skull to the nose and ears. This break in protection of the brain becomes a probable source of infection of the meninges or brain substance. There may be subconjunctival hemorrhage of the eye or periorbital ecchymosis. Skull fractures can damage the cranial nerves (I, II, III, VII, and VIII) as they exit the cranial vault.

Primary and Secondary Brain Injuries

The effects of traumatic head injuries can be divided into two categories:

1. Primary injuries, in which damage is caused by impact
2. Secondary injuries, in which damage results from the subsequent brain swelling, infection, or cerebral hypoxia

The primary brain injuries include focal (e.g., contusion, laceration, hemorrhage) and diffuse (e.g., concussion, diffuse axonal injury) injuries. Secondary brain injuries are often diffuse or multifocal, including edema, infection, and hypoxic brain damage. Although the skull and CSF provide protection for the brain, they also can contribute to trauma. When the mechanical forces inducing brain injury cause bouncing of the brain in the closed confines of the rigid skull, a contusion, coup–contrecoup injury can occur. Because the brain floats freely in the CSF, blunt force to the head accelerates the brain within the skull, and then the brain decelerates abruptly on hitting the inner skull surfaces (Fig. 20.7). The direct contusion of the brain at the site of external force is referred to as a coup injury, whereas the rebound injury on the opposite side of the brain is the contrecoup injury. As the brain strikes the rough surface of the cranial vault, brain tissue, blood vessels, nerve tracts, and other structures are bruised and torn, resulting in contusions and hematomas.
The most common cause of secondary brain injury is ischemia. It can result from the hypoxia and hypotension that occur during the resuscitation process or from the impairment of regulatory mechanisms by which cerebrovascular responses maintain an adequate blood flow and oxygen supply. Insults that occur immediately after injury or in the course of resuscitation efforts are important determinants of the outcome from severe brain injury. More than 25% of people with severe head injury sustain one or more secondary insults in the time between injury and resuscitation, indicating the need for improved airway management and circulatory status. The significance of secondary injuries depends on the extent of damage caused by the primary injury. In mild brain injury, there may be momentary loss of consciousness without noticeable neurologic symptoms or residual damage, except for possible residual amnesia. Microscopic changes usually can be detected in the neurons and glia within hours of injury, but brain imaging is negative. Concussion is a transient neurogenic dysfunction caused by some mechanical force to the brain. Although recovery usually takes place within 24 hours, mild symptoms, such as headache, irritability, insomnia, and poor concentration and memory, may persist for months. This is known as the postconcussion syndrome. The memory loss usually includes an interval of time preceding the accident (retrograde amnesia) and after the injury (anterograde amnesia). The duration of retrograde amnesia correlates with the severity of the brain injury. Because these cognitive complaints are vague and subjective, they sometimes are regarded as being of psychological origin. Postconcussion syndrome can have a significant effect on activities of daily living and return to employment. People with postconcussion syndrome may need cognitive retraining, medications, or psychological support.

In moderate brain injury, many small hemorrhages and some swelling of brain tissue occur. These contusions often are distributed along the rough, irregular inner surface of the brain and are more likely to occur in the frontal or temporal lobes, resulting in cognitive and motor deficits. Moderate brain injury is characterized by a period of unconsciousness and may be associated with focal manifestations such as hemiparesis, aphasia, and cranial nerve palsy. In this type of injury, the contusions often can be visualized on CT scan.

Severe brain injury involves extensive primary and secondary injury to brain structures. In severe head injury, the primary injury is instantaneous and irreversible, resulting from shearing and pressure forces that cause diffuse axonal injury, disruption of blood vessels, and tissue damage. Contusions and intracerebral, subdural, epidural, and subarachnoid hemorrhages are often evident on CT scan. It often is accompanied by severe neurologic deficits such as coma, hemiplegia, and elevated ICP. Severe brain injuries often occur with injury to other parts of the body such as the neck, extremities, chest, and abdomen.

**Hematomas**

Hematomas result from vascular injury and bleeding. Depending on the anatomic position of the ruptured vessel, bleeding can occur in any of several compartments, including the epidural, subdural, intracerebral, and subarachnoid spaces.
Epidural Hematoma

Epidural hematomas usually are caused by head injury in which the temporal area of the skull is fractured. An epidural hematoma is one that develops between the inner table of the bones of the skull and the dura (Fig. 20.8). It usually results from a tear in an artery, most often the middle meningeal, usually in association with a skull fracture. Because bleeding is arterial in origin, rapid expansion of the hematoma compresses the brain. Epidural hematoma is more common in a young person because the dura is less firmly attached to the skull surface than in an older person; as a consequence, the dura can be easily separated from the inner surface of the skull, allowing the hematoma to grow.

Typically, a person with an epidural hematoma presents with a history of head injury and a brief period of unconsciousness followed by a lucid period in which consciousness is regained, followed by rapid progression to unconsciousness. The lucid interval does not always occur, but when it does, it is of great diagnostic value. With rapidly developing unconsciousness, there are focal symptoms related to the area of the brain involved. These symptoms can include ipsilateral (same side) pupil dilation and contralateral (opposite side) hemiparesis from uncal herniation. If the hematoma is not removed, the condition progresses, with increased ICP, tentorial herniation, and death. However, prognosis is excellent if the hematoma is removed before loss of consciousness occurs.

Subdural Hematoma

A subdural hematoma develops in the area between the dura and the arachnoid (subdural space) and usually is the result of a tear in the small bridging veins that connect veins on the surface of the cortex to dural sinuses. The bridging veins pass from the pial vessels through the CSF-filled subarachnoid space, penetrate the arachnoid and the dura, and empty into the intradural sinuses. These veins are readily snapped in head injury when the brain moves suddenly in relation to the skull (Fig. 20.9).

The venous source of bleeding in a subdural hematoma develops more slowly than the arterial bleeding in an epidural hematoma. Subdural hematomas are classified as acute, subacute, or chronic. This classification system is based on the approximate time before the appearance of symptoms. Symptoms of acute hematoma are seen up to 48 hours after the injury, whereas subacute hematoma does not produce symptoms until 2 to 14 days after injury. Symptoms of chronic subdural hematoma may not arise until several weeks after the injury.

Acute subdural hematomas progress rapidly and have a high mortality rate because of the severe secondary injuries related to edema and increased ICP. The high mortality rate has been associated with uncontrolled ICP increase, loss of consciousness, extension posturing, and delay in surgical removal of the hematoma. The clinical picture is similar to that of epidural hematoma, except that there usually is no lucid interval. Morbidity and mortality rates are higher with acute subdural hematoma than with epidural and intracerebral hematoma. By contrast, in subacute hematoma, there may be a period of improvement in the level of consciousness and neurologic symptoms, only to be followed by deterioration if the hematoma is not removed.

Symptoms of chronic subdural hematoma develop weeks after a head injury, so much later that the person may not remember having had a head injury. Chronic subdural hematoma is more common in alcoholics and older adults because brain atrophy causes the brain to shrink away from the dura and stretch fragile bridging veins. These veins rupture, causing slow seepage of blood into the subdural space. Fibroblastic activity causes the hematoma to become encapsulated. The sanguineous fluid in this encapsulated area has high osmotic pressure and draws in fluid from the surrounding subarachnoid space; the mass expands, exerting pressure on the cranial contents. In some instances, the clinical picture is less defined, with the most prominent symptom being a decreasing level of consciousness indicated by drowsiness, confusion, headache, and apathy.

Traumatic Intracerebral Hematomas

Traumatic intracerebral hematomas may be single or multiple. They can occur in any lobe of the brain but are most common in the frontal or temporal lobes, related to the bony prominences on the inner skull surface (Fig. 20.10). They may occur in association with the severe motion that the brain undergoes during
Signs of increased ICP can be manifested if the hematoma is large and encroaching on vital structures. A hematoma in the temporal lobe can be dangerous because of the potential for lateral herniation.

The effects of traumatic brain injuries can be divided into two categories: primary and secondary injuries. Primary injuries result from direct impact, resulting in skull fracture, concussion, or contusion. In secondary injuries, damage results from the subsequent brain swelling; epidural, subdural, or intracerebral hematoma formation; infection; cerebral hypoxia; and ischemia. Even if there is no break in the skull, a blow to the head can cause severe and diffuse brain damage. Such closed injuries vary in severity and can be classified as focal or diffuse. Diffuse injuries include concussion and diffuse axonal injury. Focal injuries include contusion, laceration, and hemorrhage.
Cerebrovascular disease encompasses a number of disorders involving vessels in the cerebral circulation. These disorders include stroke and transient ischemic attacks (TIAs), and result in disruption of the cerebral circulation.

Cerebral Circulation

Cerebral Blood Vessels

The blood flow to the brain is supplied by the two internal carotid arteries anteriorly and the vertebral arteries posteriorly (Fig. 20.11A). The internal carotid artery, a terminal branch of the common carotid artery, branches into several arteries: ophthalmic, posterior communicating, anterior choroidal, anterior cerebral, and middle cerebral (see Fig. 20.11B). Most of the arterial blood in the internal carotid arteries is distributed through the anterior and middle cerebral arteries. The anterior cerebral arteries supply the medial surface of the frontal and parietal lobes and the anterior half of the thalamus, the corpus striatum, part of the corpus callosum, and the anterior limb of the internal capsule. The genu and posterior limb of the internal capsule and medial globus pallidus are fed by the anterior choroidal branch of the internal carotid artery. The middle cerebral...
artery passes laterally, supplying the lateral basal ganglia and the insula, and then emerges on the lateral cortical surface, supplying the inferior frontal gyrus, the motor and premotor frontal cortex concerned with delicate face and hand control. It is the major vascular source for the language cortices (frontal and superior temporal), the primary and association auditory cortex (superior temporal gyrus), and the primary and association somesthetes cortex for the face and hand (postcentral gyrus, parietal). The middle cerebral artery is functionally a continuance of the internal carotid; emboli of the internal carotid most frequently become lodged in branches of the middle cerebral artery. The consequences of ischemia of these areas may be the most devastating, resulting in damage to the fine manipulative skills of the face and upper limbs and to receptive and expressive communication functions (e.g., aphasia).

The two vertebral arteries arise from the subclavian artery and enter the foramina in the transverse spinal processes at the level of the sixth cervical vertebra and continue upward through the foramina of the upper six vertebrae; they wind behind the atlas and enter the skull through the foramen magnum and unite to form the basilar artery, which then diverges to terminate in the posterior cerebral arteries. Branches of the basilar and vertebral arteries supply the medulla, pons, cerebellum, midbrain, and caudal part of the diencephalon. The posterior cerebral arteries supply the remaining occipital and inferior regions of the temporal lobes and the thalamus.

The distal branches of the internal carotid and vertebral arteries communicate at the base of the brain through the circle of Willis; this anastomosis of arteries can provide continued circulation if blood flow through one of the main vessels is disrupted (see Fig. 20.10B). For instance, occlusion of one middle cerebral artery may have limited consequences if the anterior and posterior communicating arteries are patent, allowing collateral flow from the ipsilateral posterior cerebral and opposite carotid arteries. Without collateral input, cessation of blood flow in cerebral arteries results in ischemic neural damage as metabolic needs of electrically active cells exceed nutrient supply.

The cerebral circulation is drained by two sets of veins that empty into the dural venous sinuses: the deep (great) cerebral venous system and the superficial venous system. In contrast to the superficial cerebral veins that travel through the pia mater on the surface of the cerebral cortex, the deep system is well protected. These vessels connect directly to the sagittal sinuses in the falk cerebi by bridging veins. They travel through the CSF-filled subarachnoid space and penetrate the arachnoid and then the dura to reach the dural venous sinuses. This system of sinuses returns blood to the heart primarily through the internal jugular veins. Alternate routes for venous flow also exist; for example, venous blood may exit through the emissary veins that pass through the skull and through veins that traverse various foramina to empty into extracranial veins.

The intracranial venous system has no valves. The direction of flow depends on gravity or the relative pressure in the venous sinuses compared with that of the extracranial veins. Increases in intrathoracic pressure, as can occur with coughing or performance of the Valsalva maneuver (i.e., exhaling against a closed glottis), produce a rise in central venous pressure that is reflected back into the internal jugular veins and to the dural sinuses.

**Regulation of Cerebral Blood Flow**

The blood flow to the brain is maintained at approximately 750 mL/minute or one sixth of the resting cardiac output. The regulation of blood flow to the brain is controlled largely by autoregulatory or local mechanisms that respond to the metabolic needs of the brain. Cerebral autoregulation has been classically defined as the ability of the brain to maintain constant cerebral blood flow despite changes in systemic arterial pressure. This allows the cerebral cortex to adjust cerebral blood flow locally to satisfy its metabolic needs. The autoregulation of cerebral blood flow is efficient within an MAP range of approximately 60 to 140 mm Hg. Although total cerebral blood flow remains relatively stable throughout marked changes in cardiac output and arterial blood pressure, regional blood flow may vary markedly in response to local changes in metabolism. If blood pressure falls below 60 mm Hg, cerebral blood flow becomes severely compromised, and if it rises above the upper limit of autoregulation, blood flow increases rapidly and overstretches the cerebral vessels. In persons with hypertension, this autoregulatory range shifts to higher MAP levels.

At least three metabolic factors affect cerebral blood flow: carbon dioxide, hydrogen ion, and oxygen concentration. Increased carbon dioxide provides a potent stimulus for vasodilation—a doubling of the PCO₂ in the blood results in a doubling of cerebral blood flow. Increased hydrogen ion concentrations also increase cerebral blood flow, serving to wash away the neurally depressive acidic materials. Profound extracellular acidosis induces vasomotor paralysis, in which case cerebral blood flow may depend entirely on the systemic arterial blood pressure. Decreased oxygen concentration also increases cerebral blood flow.

The deep cerebral blood vessels appear to be completely controlled by autoregulation. However, the superficial and major cerebral blood vessels are innervated by the sympathetic nervous system. Under normal physiologic conditions, local regulatory and autoregulatory mechanisms override the effects of sympathetic stimulation. However, when local mechanisms fail, sympathetic control of cerebral blood pressure becomes important. For example, when the arterial pressure rises to very high levels during strenuous exercise or in other conditions, the sympathetic nervous system constricts the large and intermediate-sized superficial blood vessels as a means of protecting the smaller, more easily damaged vessels. Sympathetic reflexes are believed to cause vasospasm in the intermediate and large arteries in some types of brain damage, such as that caused by rupture of a cerebral aneurysm.

**Stroke (Brain Attack)**

Stroke is the syndrome of acute focal neurologic deficit from a vascular disorder that injures brain tissue. Stroke remains one of the leading causes of mortality and morbidity in the
United States. Each year, 795,000 Americans are afflicted with stroke; many survivors are left with at least some degree of neurologic impairment.20 The term brain attack has been promoted to raise awareness that time-dependent tissue damage occurs and that rapid emergency treatment is necessary, similar to that with heart attack.

There are two main types of strokes: ischemic and hemorrhagic. Ischemic strokes are caused by an interruption of blood flow in a cerebral vessel and are the most common type of stroke, accounting for 87% of all strokes.20 Hemorrhagic strokes account for 13% of all strokes, 10% intracerebral hemorrhage, and 3% subarachnoid hemorrhage.20 A hemorrhagic stroke usually is from a blood vessel rupture caused by hypertension, aneurysm, or arteriovenous malformation and has a much higher fatality rate than ischemic strokes.

Etiology

The risk factors for stroke are age, sex, race, prior stroke, family history, hypertension, smoking, diabetes mellitus, cardiac disease, hypercholesteremia, and hypercoagulopathy21 (Box 20.1). The incidence of stroke increases with age, with men’s stroke incidence rates being greater than women’s at younger ages, but not at older ages. Because women live longer than men, more women die of stroke each year. Blacks and some Hispanic/Latino Americans have a higher incidence of all stroke types and higher mortality rates compared with Whites.21 Blood pressure is a powerful determinant of stroke risk. The higher the blood pressure, the greater the risk of stroke.21 Heart disease, particularly atrial fibrillation and other conditions that predispose to clot formation on the wall of the heart or valve leaflets or to paradoxical embolism through right-to-left shunting, predisposes to cardioembolic stroke. Polycythemia, sickle cell disease (during sickle cell crisis), and blood disorders predispose to clot formation in the cerebral vessels.

</tbody>
</table>

Other, modifiable behavioral risk factors include obesity, physical inactivity, alcohol, illicit drug use, hypercoagulability disorders, hormone replacement therapy, and oral contraceptive use.21 An increased risk of stroke is associated with hormone replacement therapy.21 Light to moderate consumption of alcohol is associated with reduced risk of stroke, but heavier consumption of alcohol increases risk of stroke.21 Several drugs of abuse, cocaine, amphetamines, and heroin, are associated with stroke.21,22 Recent cocaine ingestion is associated with hemorrhages that occur more frequently in subcortical locations.23

Elimination or control of risk factors for stroke (e.g., use of tobacco, control of blood lipids and blood sugar, reduction of hypertension) offers the best opportunity to prevent cerebral ischemia from cerebral atherosclerosis. Primary prevention of stroke by early detection and treatment of modifiable risk factors offers significant advantages over waiting until a serious event has occurred.

Ischemic Stroke

Ischemic strokes are caused by cerebrovascular obstruction by thrombosis or emboli (Fig. 20.12). Ischemic stroke can be classified into five main mechanisms of stroke subtypes and their frequency: 20% large artery thrombosis (atherosclerotic disease), 25% small penetrating artery thrombosis disease (lacunar stroke), 20% cardiogenic embolism, 30% cryptogenic stroke (undetermined cause), and 5% other.2

Ischemic Penumbra in Evolving Stroke. During the evolution of a stroke, there usually is a central core of dead or dying cells, surrounded by an ischemic band or area of minimally perfused cells called the penumbra (border zone). Brain cells of the penumbra receive marginal blood flow, their metabolic activities are impaired, but the structural integrity of the brain cells is maintained.15 Whether the cells of the penumbra continue to survive depends on the successful timely return of adequate circulation, the volume of toxic products released by the neighboring dying cells, the degree of cerebral edema, and alterations in local blood flow. If the toxic products result in additional death of cells in the penumbra, the border zone of dead or dying tissue enlarges, and the volume of surrounding ischemic tissue increases.

Transient Ischemic Attacks. TIAs are a transient episode of neurological dysfunction caused by focal brain, spinal cord, or retinal ischemia, without acute infarction.24 A TIA reflects a temporary disturbance in focal cerebral blood flow, which reverses before infarction occurs. The causes of TIAs are the same as those of ischemic stroke and include atherosclerotic disease of cerebral vessels and emboli. TIAs are important because they may provide warning of impending stroke. There is a higher risk of early stroke after TIA, 10% to 15% have a stroke within 3 months, with 50% occurring in 48 hours.24 Diagnosis of TIA before a stroke may permit surgical or medical intervention that prevents an eventual stroke and the associated neurologic deficits.
Large-Vessel (Thrombotic) Stroke. Thrombi are the most common cause of ischemic strokes, usually occurring in atherosclerotic blood vessels. In the cerebral circulation, atherosclerotic plaques are found most commonly at arterial bifurcations. Common sites of plaque formation include larger vessels of the brain, notably the origins of the internal carotid and vertebral arteries, and junctions of the basilar and vertebral arteries. Cerebral infarction can result from an acute local thrombosis and occlusion at the site of chronic atherosclerosis, with or without embolization of the plaque material distally, or from critical perfusion failure distal to a stenosis (watershed). These infarcts often affect the cortex, causing aphasia or neglect, visual field defects, or transient monocular blindness (amaurosis fugax). In most cases of stroke, a single cerebral artery and its territories are affected. Usually, thrombotic strokes are seen in older persons and frequently are accompanied by evidence of atherosclerotic heart or peripheral arterial disease.

Small-Vessel Stroke (Lacunar Infarct). Lacunar infarcts are small (1.5- to 2-cm) to very small (3- to 4-mm) infarcts located in the deeper, noncortical parts of the brain or in the brain stem. They are found in the territory of single deep penetrating arteries supplying the internal capsule, basal ganglia, or brain stem. They result from occlusion of the smaller penetrating branches of large cerebral arteries, commonly the middle cerebral and posterior cerebral arteries. In the process of healing, lacunar infarcts leave behind small cavities, or lacunae (“lakes”). They are thought to result from arteriolar lipohyalinosis or microatheroma, commonly in the settings of chronic hypertension or diabetes. Six basic causes of lacunar infarcts have been proposed: embolism, hypertension, small-vessel occlusive disease, hematologic abnormalities, small intracerebral hemorrhages, and vasospasm. Because of their size and location, lacunar infarcts usually do not cause cortical deficits like aphasia or apraxia. Instead, they produce classic recognizable “lacunar syndromes” such as pure motor hemiplegia, pure sensory hemiplegia, and dysarthria with the clumsy hand syndrome. CT or MRI may show several lacunae as well as diffuse white matter changes associated with dementia.

Cardiogenic Embolic Stroke. An embolic stroke is caused by a moving blood clot that travels from its origin to the brain. It usually affects the larger proximal cerebral vessels, often lodging at bifurcations. The most frequent site of embolic strokes is the middle cerebral artery, reflecting the large territory of this vessel and its position as the terminus of the carotid artery. Although most cerebral emboli originate from a thrombus in the left heart, they also may originate in an atherosclerotic plaque in the carotid arteries. The embolus travels quickly to the brain and becomes lodged in a smaller artery through which it cannot pass. Embolic stroke usually has a sudden onset with immediate maximum deficit.

Various cardiac conditions predispose to formation of emboli that produce embolic stroke, including rheumatic heart disease, atrial fibrillation, recent myocardial infarction, ventricular aneurysm, mobile aortic arch atheroma, and bacterial endocarditis. The use of transesophageal echocardiography has implicated a patent foramen ovale as a source for paradoxical venous emboli to the arterial system.
Hemorrhagic Stroke

The most frequently fatal stroke results from the spontaneous rupture of a cerebral blood vessel. The resulting intracerebral hemorrhage can cause a focal hematoma, edema, compression of the brain contents, or spasm of the adjacent blood vessels (Fig. 20.13). The most common predisposing factors are advancing age and hypertension. Other causes of hemorrhage are trauma, erosion of the vessels by tumors, blood coagulation disorders, vasculitis, and drugs. Aneurysms and arteriovenous malformations are structural abnormalities that can also cause sudden hemorrhage. A cerebral hemorrhage occurs suddenly, usually when the person is active. Vomiting commonly occurs at the onset, and headache often occurs. Focal symptoms depend on which vessel is involved. In the most common situation, hemorrhage into the basal ganglia results in contralateral hemiplegia, with initial flaccidity progressing to spasticity. The hemorrhage and resultant edema exert great pressure on the brain substance, and the clinical course progresses rapidly to coma and frequently to death.

Aneurysmal Subarachnoid Hemorrhage. Aneurysmal subarachnoid hemorrhage is a type of hemorrhagic stroke caused by the rupture of a cerebral aneurysm and the resulting bleeding into the subarachnoid space can extend well beyond the site of origin, flooding the basal cistern, ventricles, and spinal subarachnoid space. An aneurysm is a bulge at the site of a localized weakness in the muscular wall of an arterial vessel. Most cerebral aneurysms are small saccular aneurysms called berry aneurysms. They usually occur in the anterior circulation and are found at bifurcations and other junctions of vessels such as those in the circle of Willis (Fig. 20.14). They are thought to arise from a congenital defect in the media of the involved vessels. Their incidence is higher in people with certain disorders, including polycystic kidney disease, fibromuscular dysplasia, coarctation of the aorta, and arteriovenous malformations of the brain. Other causes of cerebral aneurysms are atherosclerosis, hypertension, and bacterial infections.

Rupture of a cerebral aneurysm results in subarachnoid hemorrhage. The probability of rupture increases with the size of the aneurysm, more likely in those bigger than 3 to 5 mm. Of the various environmental factors that may predispose to aneurysmal subarachnoid hemorrhage, cigarette smoking, hypertension, and excessive alcohol intake appear to constitute the greatest threat. Intracranial aneurysms are rare in children, and the mean age for subarachnoid hemorrhage is approximately 50 years. The mortality and morbidity rates with aneurysmal subarachnoid hemorrhage are high, with only one third of people recovering without major disability.

Clinical Manifestations. The signs and symptoms of cerebral aneurysms can be divided into two phases: those presenting before rupture and bleeding and those presenting after rupture and bleeding. Most small aneurysms are asymptomatic. Intact aneurysms frequently are found at autopsy as an incidental finding. Approximately 10% to 20% of people with subarachnoid hemorrhage have a history of atypical headaches occurring days to weeks before the onset of hemorrhage, suggesting the presence of a small leak. These headaches are characterized by sudden onset and often are accompanied by nausea, vomiting, and dizziness. The onset of subarachnoid aneurysmal rupture often is heralded by a sudden and severe headache, described as “the worst headache of my life.” If the bleeding is severe, the headache may be accompanied by collapse and loss of consciousness. Vomiting may accompany the presenting symptoms. Other manifestations include signs of meningeal irritation such as nuchal rigidity (neck stiffness) and photophobia (light intolerance); cranial nerve deficits, especially cranial nerve II, and sometimes III and IV (diplopia and blurred vision); stroke syndromes (focal motor and sensory deficits); cerebral edema and increased
ICP; and pituitary dysfunction (diabetes insipidus and hyponatremia). Hypertension, a frequent finding, and cardiac arrhythmias result from massive release of catecholamines triggered by the subarachnoid hemorrhage.

**Diagnosis.** The diagnosis of subarachnoid hemorrhage and intracranial aneurysms is made by clinical presentation, noncontrast CT scan, lumbar puncture if CT is normal and suspicion of SAH is strong, and angiography.²⁸,²⁹ To identify the aneurysm at the source of bleeding, conventional angiography, magnetic resonance angiography (MRA), and helical (spiral) computed tomography angiography (CTA) are used. Conventional catheter angiography is the definitive diagnostic tool for detecting the aneurysm. MRA is noninvasive and does not require the intravascular administration of contrast, but is less sensitive. Helical CTA does require intravenous contrast, but can be used in persons after aneurysmal clipping, when the use of MRI may be contraindicated.

**Treatment.** The course of treatment after aneurysm rupture depends on the extent of neurologic deficit. The best outcomes are achieved when the aneurysm can be secured early and prevention of complications initiated.²⁹,³⁰,³¹ People with mild to no neurologic deficits may undergo cerebral arteriography and early surgery, usually within 24 to 72 hours. Surgery involves craniotomy and inserting a specially designed silver clip that is tightened around the neck of the aneurysm. This procedure offers protection from rebleeding. Endovascular coiling is an alternative to surgery, particularly in surgically inaccessible aneurysms or poor surgical candidates. The complications of aneurysmal rupture include rebleeding, vasospasm with cerebral ischemia, hydrocephalus, hypothalamic dysfunction, and seizure activity. Rebleeding and vasospasm are the most serious and most difficult to treat. Rebleeding, which has its highest incidence on the first day after the initial rupture, results in further and usually catastrophic neurologic deficits.

Vasospasm is a dreaded complication of aneurysmal rupture. The condition is difficult to treat and is associated with a high incidence of morbidity and mortality. Although the description of aneurysm-associated vasospasm is relatively uniform, its proposed mechanisms are controversial. Usually, the condition develops within 3 to 10 days (peak, 7 days) after aneurysm rupture and involves a focal narrowing of the cerebral artery or arteries that can be visualized on arteriography or by transcranial Doppler. The neurologic status gradually deteriorates as blood supply to the brain in the region of the spasm is decreased; this usually can be differentiated from the rapid deterioration seen in rebleeding. Vasospasm is treated by attempting to improve CPP through the use of vasoactive drugs or administration of intravenous fluids to increase intravascular volume and produce hemodilution. Endovascular techniques include intra-arterial vasodilators and mechanical dilatation of vessels with balloon angioplasty. Nimodipine, a drug that blocks calcium channels and selectively acts on cerebral blood vessels, may be used to reduce the incidence and severity of delayed ischemic deficits from vasospasm following aneurysmal rupture.

Another complication of aneurysm rupture is the development of hydrocephalus. It is caused by plugging of the arachnoid villi with products from lysis of blood in the subarachnoid space. Hydrocephalus is diagnosed by serial CT scans showing increasing size of the ventricles and by the clinical signs of increased ICP. Hydrocephalus may respond to osmotic diuretics, but if neurologic deterioration is significant, surgical placement of a shunt is indicated.

**Arteriovenous Malformations.** Arteriovenous malformations are a complex tangle of abnormal arteries and veins linked by one or more fistulas.² These vascular networks lack a capillary bed, and the small arteries have a deficient muscularis layer. Arteriovenous malformations are thought to arise from failure in development of the capillary network in the embryonic brain. As the child’s brain grows, the malformation acquires additional arterial contributions that enlarge to form a tangled collection of thin-walled vessels that shunt blood directly from the arterial to the venous circulation. Arteriovenous malformations typically present before 40 years of age and affect men and women equally. Rupture of vessels in the malformation causing hemorrhagic stroke accounts for approximately 1% of all strokes.

**Pathophysiology.** The hemodynamic effects of arteriovenous malformations are twofold. First, blood is shunted from the high-pressure arterial system to the low-pressure venous system without the buffering advantage of the capillary network. The draining venous channels are exposed to high levels of pressure, predisposing them to rupture and hemorrhage. Second, the elevated arterial and venous pressures divert blood away from the surrounding tissue, impairing tissue perfusion.

**Clinical Manifestations.** Clinically, this is evidenced by slowly progressive neurologic deficits. The major clinical manifestations of arteriovenous malformations are intracerebral and subarachnoid hemorrhage, seizures, headache, and progressive neurologic deficits. Headaches often are severe, and people with the disorder may describe them as throbbing and synchronous with their heartbeat. Other, focal symptoms depend on the location of the lesion and include visual symptoms (i.e., diplopia and hemianopia), hemiparesis, mental deterioration, and speech deficits.

**Diagnosis and Treatment.** Definitive diagnosis often is obtained through cerebral angiography. Treatment methods include surgical excision, endovascular occlusion, radiosurgery, and conservative treatment.² Because of the nature of the malformation, each of these methods is accompanied by some risk for complications. If the arteriovenous malformation is accessible, surgical excision usually is the treatment of choice. Endovascular treatment involves the insertion of microwires into the cerebral circulation for delivery of embolic materials (e.g., microspheres, sclerosing agents, microcoils, or quick-drying glue) into the arteriovenous malformation vessels.²⁴⁵
Radiosurgery may involve the use of a gamma knife, proton beam, or linear accelerator.

**Clinical Manifestations of Stroke**

The specific manifestations of stroke or TIA are determined by the cerebral artery that is affected, by the area of brain tissue that is supplied by that vessel, and by the adequacy of the collateral circulation. Symptoms of stroke/TIA always are sudden in onset and focal and usually are one-sided. The most common symptoms are a facial droop, arm weakness, and slurred speech. Other frequent stroke symptoms are unilateral numbness, vision loss in one eye (amaurosis fugax) or to one side (hemianopia), language disturbance (aphasia), and sudden, unexplained imbalance or ataxia. In the event of TIA, symptoms rapidly resolve spontaneously, usually within minutes, although the underlying mechanisms are the same as for stroke. The specific stroke signs depend on the specific vascular territory compromised (Table 20.6). As a generalization, carotid ischemia causes monocular visual loss or aphasia (dominant hemisphere) or hemineglect (nondominant hemisphere), contralateral sensory or motor loss, or other discrete cortical signs such as apraxia and agnosia. Vertebrobasilar ischemia induces ataxia, diplopia, hemianopia, vertigo, cranial nerve deficits, contralateral hemiplegia, sensory deficits (either contralateral or crossed, i.e., contralateral body and ipsilateral face), and arousal defects. Discrete subsets of these vascular syndromes usually occur, depending on which branches of the involved artery are blocked.

*Depend on hemisphere involved and adequacy of collaterals.

**Stroke-Related Motor Deficits.** Motor deficits are most common, followed by deficits of language, sensation, and cognition. After a stroke affecting the corticospinal tract such as the motor cortex, posterior limb of the internal capsule, basis pontis, or medullary pyramids, there is profound weakness on the contralateral side. Involvement at the level of the motor cortex is most often in the territory of the middle cerebral artery, usually with a sparing of the leg, which is supplied by the anterior cerebral artery. Subcortical lesions of the corticospinal tracts cause equal weakness of the face, arm, and leg. Within 6 to 8 weeks, the initial weakness and flaccidity is replaced by hyperreflexia and spasticity. Spasticity involves an increase in the tone of affected muscles and usually an element of weakness. The flexor muscles usually are more strongly affected in the upper extremities and the extensor muscles more strongly affected in the lower extremities. There is a tendency toward foot drop; outward rotation and circumduction of the leg with gait; flexion at the wrist, elbow, and fingers; lower facial paresis; slurred speech; an upgoing toe to plantar stimulation (Babinski sign); and dependent edema in the affected extremities. A slight corticospinal lesion may be indicated only by clumsiness in carrying out fine coordinated movements rather than obvious weakness. Passive range-of-motion exercises help to maintain joint function and to prevent edema, shoulder subluxation (i.e., incomplete dislocation), and muscle atrophy and may help to reestablish motor patterns. If no voluntary movement or movement on command appears within a few months, significant function usually will not return to that extremity.
**Stroke-Related Dysarthria and Aphasia.** Dysarthria is a disorder of speech, manifest as the imperfect articulation of speech sounds or changes in voice pitch or quality. It results from a stroke affecting the muscles of the pharynx, palate, tongue, lips, or mouth and does not relate to the content of speech. A person with dysarthria may demonstrate slurred speech while still retaining language ability or have a concurrent language problem as well. Aphasia is a general term that encompasses varying degrees of inability to comprehend, integrate, and express language. Aphasia may be localized to the dominant cerebral cortex or thalamus, usually the left side in 95% of people who are right handed and 70% of people who are left handed. In children, language dominance can readily shift to the unaffected hemisphere, resulting in more transient language deficits after stroke. A stroke in the territory of the middle cerebral artery is the most common aphasia-producing stroke.

Aphasia can be categorized as receptive or expressive, or as fluent or nonfluent. Fluency relates to the ease and spontaneity of conversational speech and is more strictly defined by the rate of speech, with “fluent” denoting many words and “nonfluent,” few words. Expressive or nonfluent aphasia is characterized by an inability easily to communicate spontaneously or translate thoughts or ideas into meaningful speech or writing. Speech production is limited, effortful, and halting and often may be poorly articulated because of a concurrent dysarthria. The person may be able, with difficulty, to utter or write two or three words, especially those with an emotional overlay. Comprehension is normal, and the person seems to be fully aware of his or her deficits but is unable to correct them. This often leads to frustration, anger, and depression. Expressive, nonfluent aphasia is associated with lesions of the Broca area at the dominant inferior frontal lobe cortex (areas 44 and 45).

Fluent speech requires little or no effort, is articulate, and is of increased quantity. The term fluent refers only to the ease and rate of verbal output and does not relate to the content of speech or the ability of the person to comprehend what is being said. Verbal utterances are often paraphasic, meaning that letters, syllables, or whole words are substituted for the target words. There are three categories of fluent aphasia: Wernicke, anomic, and conductive aphasia. Wernicke aphasia is characterized by an inability to comprehend the speech of others or to comprehend written material. Lesions of the posterior superior temporal or lower parietal lobe (areas 22 and 39) are associated with receptive, fluent aphasia. Anomic aphasia is speech that is nearly normal except for a difficulty with finding singular words. Conductive aphasia is manifest as impaired repetition and speech riddled with letter substitutions, despite good comprehension and fluency. Conductive aphasia (i.e., disconnection syndrome) results from destruction of the fiber system under the insula that connects the Wernicke and Broca areas.

**Stroke-Related Cognitive and Other Deficits.** Stroke can also cause cognitive, sensory, visual, and behavioral deficits. One distinct cognitive syndrome is that of hemineglect or hemi-inattention. Usually caused by strokes affecting the nondominant (right) hemisphere, hemineglect is the inability to attend to and react to stimuli coming from the contralateral (left) side of space. People may not visually track, orient, or reach to the neglected side. They may neglect to use the limbs on that side, despite normal motor function, and may not shave, wash, or comb that side. Such people are unaware of this deficit, which is another form of their neglect (anosognosia). Other cognitive deficits include apraxia (impaired ability to carry out previously learned motor activities despite normal sensory and motor function), agnosia (impaired recognition with normal sensory function), memory loss, behavioral syndromes, and depression. Sensory deficits affect the body contralateral to the lesion and can manifest as numbness, tingling paresthesias, or distorted sensations such as dysesthesia and neuropathic pain. Visual disturbances from stroke are diverse, but most common are hemianopia from a lesion of the optic radiations between the lateral geniculate body and the temporal or occipital lobes, or monocular blindness from occlusion of the ipsilateral central retinal artery, a branch of the internal carotid.

**Diagnosis and Treatment of Stroke**

**Diagnosis.** Accurate diagnosis of acute stroke is based on a complete history and neurologic examination. A careful history, including documentation of previous TIAs, the time of onset, the specific focal symptoms (to determine the likely vascular territory), and any coexisting diseases, can help to determine the type of stroke that is involved. The diagnostic evaluation should aim to determine the presence of ischemia or hemorrhage, identify the stroke or TIA mechanism (i.e., large-vessel or small-vessel atherothrombotic, cardioembolic, hemorrhagic, other or cryptogenic), characterize the severity of clinical deficits, and unmask the presence of risk factors.

Brain imaging studies document the brain infarction, whereas vascular imaging reveals the anatomy and pathologic processes of the related blood vessels. CT scans and MRI have become essential brain imaging tools in diagnosing stroke, differentiating cerebral hemorrhage from ischemia, and excluding intracranial lesions that mimic stroke clinically. CT scans are a necessary screening tool in the acute setting for rapid identification of hemorrhage, but are insensitive to ischemia within 24 hours and to any brain stem or small infarcts. MRI is superior for imaging ischemic lesions in all territories and differentiating other nonstroke pathologic processes (e.g., tumors, contusion, infection). MRI techniques such as perfusion- and diffusion-weighted imaging (DWI) can reveal cerebral ischemia immediately after onset and identify areas of potentially reversible damage (i.e., penumbra). MR DWI is used in settings of emergency stroke evaluation to rapidly identify the area and volume of ischemia, identifying candidates for emergency treatments.

Vascular imaging is accomplished with CTA, MRA, catheter-based “conventional” arteriography, and ultrasonography. All except ultrasonography can demonstrate the site of vascular abnormality (intracranial and extracranial) and afford visualization of most intracranial vascular areas. However,
each modality has relative strengths and weaknesses. MRA is noninvasive and most widely available, but less sensitive and specific than CTA or catheter angiography. CTA is exquisitely detailed for a noninvasive technique, but is limited in availability and requires iodinated contrast, which is nephrotoxic. Catheter angiography remains the gold standard in sensitivity and allows visualization of dynamic patterns of collateral flow, but is invasive and requires significant contrast doses. CTA and MRA have largely replaced angiography as a screening tool for vascular lesions. Ultrasonographic techniques allow quick bedside assessment of the carotid bifurcation (duplex ultrasonography) or of flow velocities in the cerebral circulation (transcranial Doppler).

**Treatment.** Salvaging brain tissue, preventing secondary stroke, and minimizing long-term disability are the treatment goals for an acute ischemic stroke. The care of patients with stroke has shifted away from the “nearest hospital” to certified stroke centers. These are hospitals that have been certified by some external agency, most commonly the state or Joint Commission on Accreditation of Healthcare Organizations, the federal agency overseeing all facilities that care for Medicare patients.\(^2\) Certification establishes that a hospital can manage stroke patients with appropriate care throughout the continuum, from emergency treatments, through the inpatient stay, and into the rehabilitation phase. With this advancement, the medical and lay communities together acknowledge that care of the person with stroke requires specialized personnel and resources to minimize the devastating costs to society from stroke, the leading cause of adult disability in the United States.

Stroke care begins with emergency treatments aimed at reversing the evolving ischemic brain injury. The realization that there is a window of opportunity during which ischemic but viable brain tissue can be salvaged has led to the use of reperfusion techniques and neuroprotective strategies in the early treatment of ischemic stroke. Although the results of emergent treatment of hemorrhagic stroke have been less dramatic, continued efforts to reduce disability have been promising. Reperfusion techniques include thrombolytic drugs (administered either intravenously or intra-arterially), catheter-directed mechanical clot disruption, and augmentation of CPP during acute stroke. The use of thrombolytic agents for treatment of stroke was first investigated in the late 1960s, but it was quickly abandoned because of hemorrhagic complications resulting from treatment many hours beyond the time window of penumbral cell viability and because exclusion of people with hemorrhagic stroke was difficult before CT scanning was available. The interest in thrombolytic therapy has increased because of thrombolytic agents and the availability of rapid diagnostic scanning methods that are able to differentiate between ischemic and hemorrhagic stroke.

The first and only agent approved by the U.S. Food and Drug Administration (FDA) for treatment of acute ischemic stroke is tissue plasminogen activator (tPA), which was approved in 1996. A subcommittee of the Stroke Council of the American Heart Association has developed guidelines for the use of tPA for acute stroke.\(^14\) These guidelines recommend that in persons with suspected stroke, the diagnosis of hemorrhagic stroke be excluded through the use of CT scanning before administration of thrombolytic therapy, which must be administered within 3 hours of onset of symptoms. The major risk of treatment with thrombolytic agents is intracranial hemorrhage. A number of conditions, including therapeutic levels of oral anticoagulant medications, a history of gastrointestinal or urinary tract bleeding in the previous 21 days, prior stroke or head injury within 3 months, major surgery within the past 14 days, and a blood pressure greater than 185/110 mm Hg, are considered contraindications to intravenous thrombolytic therapy.\(^14\) A longer time window for treatment with tPA has been tested formally and should be administered to eligible people who can be treated in the time period of 3 to 4.5 hours after stroke.\(^33\)

Emerging treatments for ischemic stroke are being increasingly used as alternative methods of reperfusion beyond intravenous thrombolysis. Catheter-based methods allow recanalization of a directly visualized cerebral clot with intra-arterial techniques. The interventional specialist might mechanically disrupt the clot, deliver thrombolytic drug intra-arterially at the clot surface, or urgently stent intracranial vessels to restore flow. Generally, although patient selection is more stringent for these invasive methods, patients can be treated past the 3-hour time window for intravenous tPA. However, these methods require an experienced interventional angiography team and extensive institutional infrastructure and thus remain limited to tertiary care centers. Other experimental treatments include neuroprotection with drugs that limit the calcium cascade (see Fig. 20.4), and treatments like hypothermia that decrease brain metabolic demands in the setting of ischemia are being actively investigated in clinical trials.

Poststroke treatment is aimed at preventing recurrent stroke and medical complications, while promoting the fullest possible recovery of function. The risk of stroke recurrence is highest in the first week after stroke or TIA, so the early implementation of antiplatelet agents in most cases, or warfarin (an anticoagulant) in cardioembolic stroke, is imperative. Long-term stroke recurrence is most effectively prevented with aggressive reduction of risk factors, primarily hypertension, diabetes, smoking, and hyperlipidemia. In cases of carotid territory stroke with carotid stenosis, revascularization with surgery or stenting should be considered. Early hospital care also requires careful prevention of aspiration, deep vein thrombosis, and falls. Recovery is maximized with early and aggressive rehabilitation efforts that include all members of the rehabilitation team—physician, nurse, speech therapist, physical therapist, and occupational therapist—and the family. The successful treatment of stroke depends on education of the public, paramedics, and health care professionals about the need for both early diagnosis and treatment and for risk factor reduction and prevention. The message should be that prevention is the key and to treat stroke symptoms as an emergency “brain attack.” Effective medical and surgical procedures may preserve brain function and prevent disability.
A stroke, or “brain attack,” is an acute focal neurologic deficit caused by a vascular disorder that injures brain tissue. It is the fourth leading cause of death in the United States and a major cause of disability. There are two main types of stroke: ischemic and hemorrhagic. Ischemic stroke, which is the most common type, is caused by cerebrovascular obstruction by a thrombus or emboli. Hemorrhagic stroke, which is associated with greater morbidity and mortality, is caused by the rupture of a blood vessel and bleeding into the brain.

One form of hemorrhagic stroke, known as aneurysmal subarachnoid hemorrhage, results from a ruptured cerebral aneurysm. Presenting symptoms include worst headache of life, nuchal rigidity, photophobia, and nausea. Complications include rebleeding, vasospasm, and hydrocephalus.

Arteriovenous malformations are congenital abnormal communications between arterial and venous channels that result from failure in development of the capillary network in the embryonic brain. The vessels in the arteriovenous malformations may enlarge to form a space-occupying lesion, become weak and predisposed to bleeding, and divert blood away from other parts of the brain; they can cause brain hemorrhage, seizures, headache, and other neurologic deficits.

The acute manifestations of stroke depend on the location of the blood vessel that is involved and can include motor, sensory, language, speech, and cognitive disorders. Early diagnosis and treatment with thrombolytic agents can prevent disabling brain injury from ischemic stroke. Treatment of long-term neurologic deficits from stroke is primarily symptomatic, involving the combined efforts of the health care team, the patient, and the family.

**Chapter 20 Disorders of Brain Function**

They also may be classified by the type of invading organism, including bacterial, viral, fungal, or other. In general, pathogens enter the CNS through the bloodstream by crossing the blood–brain barrier or by direct invasion through skull fracture or a bullet hole or, rarely, by contamination during surgery or lumbar puncture.

**Meningitis**

Meningitis is an inflammation of the pia mater, the arachnoid, and the CSF-filled subarachnoid space. Inflammation spreads rapidly because of CSF circulation around the brain and spinal cord. The inflammation usually is caused by an infection, but chemical meningitis can occur. There are two types of acute infectious meningitis: acute purulent meningitis (usually bacterial) and acute lymphocytic (usually viral) meningitis. Factors responsible for the severity of meningitis include virulence factors of the pathogen, host factors, brain edema, and the presence of permanent neurologic sequelae.

**Bacterial Meningitis.** Most cases of bacterial meningitis are caused by Streptococcus pneumoniae (the pneumococcus) or Neisseria meningitidis (the meningococcus), except in neonates (infected most by group B streptococci). Other pathogens that cause infection in adults are gram-negative bacilli and Listeria monocytogenes. Haemophilus influenzae was a leading cause of meningitis in decades. However, incidence of infection caused by this organism has declined dramatically during recent years because of vaccination against H. influenzae.

Epidemics of meningococcal meningitis occur in settings such as the military, where the recruits must reside in close contact. The very young and the very old are at highest risk for pneumococcal meningitis. Risk factors associated with contracting meningitis include head trauma with basilar skull fractures, otitis media, sinusitis or mastoiditis, neurosurgery, dermal sinus tracts, systemic sepsis, or immunocompromise.

**Pathophysiology.** In the pathophysiologic process of bacterial meningitis, the bacterial organisms replicate and undergo lysis in the CSF, releasing endotoxins or cell wall fragments. These substances initiate the release of inflammatory mediators, which set off a complex sequence of events permitting pathogens, neutrophils, and albumin to move across the capillary wall into the CSF. As the pathogens enter the subarachnoid space, they cause inflammation, characterized by a cloudy, purulent exudate. Thrombophlebitis of the bridging veins and dural sinuses or obliteration of arterioles by inflammation may develop, causing vascular congestion and infarction in the surrounding tissues. Ultimately, the meninges thicken and adhesions form. These adhesions may impinge on the cranial nerves, giving rise to cranial nerve palsies, or may impair the outflow of CSF, causing hydrocephalus.

**Clinical Manifestations.** The most common symptoms of acute bacterial meningitis are fever and chills; headache; stiff neck; back, abdominal, and extremity pains; and nausea.

**INFECTIONS AND NEOPLASMS**

After completing this section of the chapter, you should be able to meet the following objectives:

- Discuss the assessment and management of meningitis.
- Describe the symptoms of encephalitis.
- Identify the classification of major brain tumors.
- Describe the general clinical manifestations of brain tumors.

**Infections**

Infections of the CNS may be classified according to the structure involved, including

- Meninges—meningitis
- Brain parenchyma—encephalitis
- Spinal cord—myelitis
- Brain and spinal cord—encephalomyelitis

**Meningitis**

Meningitis is an inflammation of the pia mater, the arachnoid, and the CSF-filled subarachnoid space. Inflammation spreads rapidly because of CSF circulation around the brain and spinal cord. The inflammation usually is caused by an infection, but chemical meningitis can occur. There are two types of acute infectious meningitis: acute purulent meningitis (usually bacterial) and acute lymphocytic (usually viral) meningitis. Factors responsible for the severity of meningitis include virulence factors of the pathogen, host factors, brain edema, and the presence of permanent neurologic sequelae.

**Bacterial Meningitis.** Most cases of bacterial meningitis are caused by Streptococcus pneumoniae (the pneumococcus) or Neisseria meningitidis (the meningococcus), except in neonates (infected most by group B streptococci). Other pathogens that cause infection in adults are gram-negative bacilli and Listeria monocytogenes. Haemophilus influenzae was a leading cause of meningitis in decades. However, incidence of infection caused by this organism has declined dramatically during recent years because of vaccination against H. influenzae.

Epidemics of meningococcal meningitis occur in settings such as the military, where the recruits must reside in close contact. The very young and the very old are at highest risk for pneumococcal meningitis. Risk factors associated with contracting meningitis include head trauma with basilar skull fractures, otitis media, sinusitis or mastoiditis, neurosurgery, dermal sinus tracts, systemic sepsis, or immunocompromise.

**Pathophysiology.** In the pathophysiologic process of bacterial meningitis, the bacterial organisms replicate and undergo lysis in the CSF, releasing endotoxins or cell wall fragments. These substances initiate the release of inflammatory mediators, which set off a complex sequence of events permitting pathogens, neutrophils, and albumin to move across the capillary wall into the CSF. As the pathogens enter the subarachnoid space, they cause inflammation, characterized by a cloudy, purulent exudate. Thrombophlebitis of the bridging veins and dural sinuses or obliteration of arterioles by inflammation may develop, causing vascular congestion and infarction in the surrounding tissues. Ultimately, the meninges thicken and adhesions form. These adhesions may impinge on the cranial nerves, giving rise to cranial nerve palsies, or may impair the outflow of CSF, causing hydrocephalus.

**Clinical Manifestations.** The most common symptoms of acute bacterial meningitis are fever and chills; headache; stiff neck; back, abdominal, and extremity pains; and nausea.
and vomiting. Other signs include seizures, cranial nerve palsies, and focal cerebral signs. Meningococcal meningitis causes a petechial rash with palpable purpura in most people. These petechiae vary in size from pinhead to large ecchymoses or even areas of skin gangrene that slough if the person survives. Other types of meningitis also may produce a petechial rash. Persons infected with H. influenzae or S. pneumoniae may present with difficulty in arousal and seizures, whereas those with N. meningitidis infection may present with delirium or coma. The development of brain edema, hydrocephalus, or increased cerebral blood flow can increase ICP.

Meningeal signs (e.g., photophobia and nuchal rigidity), such as those seen in subarachnoid hemorrhage, also may be present. Two assessment techniques can help determine whether meningeal irritation is present. The Kernig sign is resistance to extension of the knee while the person is lying with the hip flexed at a right angle. The Brudzinski sign is elicited when flexion of the neck induces flexion of the hip and knee. These postures reflect resistance to the painful stretching of the inflamed meninges from the lumbar level to the head. Cranial nerve damage (especially the eighth nerve, with resulting deafness) and hydrocephalus may occur as complications of pyogenic meningitis.

**Diagnosis.** Diagnosis of bacterial meningitis is based on the history and physical examination, along with laboratory data. Lumbar puncture findings, which are necessary for accurate diagnosis, include a cloudy and purulent CSF under increased pressure. The CSF typically contains large numbers of polymorphonuclear neutrophils (up to 90,000/mm³), increased protein content, and reduced sugar content. Bacteria can be seen on smears and can easily be cultured with appropriate media. Occasionally, previous antibiotic use limits culture sensitivities, in which case latex agglutination can be used, or polymerase chain reaction (PCR) testing for N. meningitidis, H. influenzae, and Listeria species. Because complications associated with lumbar puncture include life-threatening cerebral herniation, at-risk patients (i.e., those who are immunocompromised, had a seizure within a week, have papilledema, or have specific neurologic abnormalities) should have a CT scan before undergoing the procedure.

**Treatment.** Treatment includes urgent antibiotics while diagnostic testing ensues. Delay in initiation of antimicrobial therapy, most frequently because of performance of medical imaging before performance of lumbar puncture or transfer to another medical facility, can result in poor outcomes. Initial choice of antibiotics includes broad-spectrum coverage with a third-generation cephalosporin, vancomycin, and sometimes ampicillin. Further adjustment of antibiotics is driven by results of CSF cultures. Effective antibiotics produce rapid lysis of the pathogen, which produces inflammatory mediators that have the potential for exacerbating the abnormalities of the blood–brain barrier. To suppress this pathologic inflammation, adjunctive corticosteroid therapy is increasingly administered with or just before the first dose of antibiotics in patients of all ages.

People who have been exposed to someone with meningococcal meningitis should be treated prophylactically with antibiotics. Effective polysaccharide vaccines are available to protect against meningococcal groups A, C, Y, and W-135. These vaccines are recommended for military recruits and college students, who are at increased risk for invasive meningococcal disease.

**Viral Meningitis.** Viral meningitis manifests in much the same way as bacterial meningitis, but the course is less severe and the CSF findings are markedly different. There are lymphocytes in the fluid rather than polymorphonuclear cells, the protein content is only moderately elevated, and the sugar content usually is normal. The acute viral meningitides are self-limited and usually require only symptomatic treatment, except for herpes simplex virus (HSV) type 2, which responds to intravenous acyclovir. Viral meningitis can be caused by many different viruses, most often enteroviruses, including coxsackievirus, poliovirus, and echovirus. Others include Epstein-Barr virus, mumps virus, HSV, and West Nile virus. Although often the virus cannot be identified, newer assays are emerging that allow in some circumstances for rapid identification of viral ribonucleic acid (RNA) in CSF.

**Encephalitis**

Encephalitis represents a generalized infection of the parenchyma of the brain or spinal cord. A virus usually causes it, but it also may be caused by bacteria, fungi, and other organisms. The nervous system is subject to invasion by many viruses, such as arbovirus, poliovirus, and rabies virus. The mode of transmission may be the bite of a mosquito (arbovirus), a rabid animal (rabies virus), or ingestion (poliovirus). Common causes of encephalitis in the United States are HSV and West Nile virus. Less frequent causes of encephalitis are toxic substances such as ingested lead and vaccines for measles and mumps.

The pathologic picture of encephalitis includes local necrotizing hemorrhage, which ultimately becomes generalized, with prominent edema. There is progressive degeneration of nerve cell bodies. The histologic picture, although rather general, may demonstrate some specific characteristics. For example, the poliovirus selectively destroys the cells of the anterior horn of the spinal cord.

Like meningitis, encephalitis is characterized by fever, headache, and nuchal rigidity. However, more often, people also experience neurologic disturbances, such as lethargy, disorientation, seizures, focal paralysis, delirium, and coma. Diagnosis of encephalitis is made by clinical history and presenting symptoms, in addition to traditional CSF studies.

**Brain Tumors**

Primary brain tumors account for 2% of all cancer deaths. The American Cancer Society estimates that there were 22,340 new cases and more than 13,110 deaths from brain
and other nervous system cancers in 2011.\textsuperscript{36} Metastases to the brain develops in 10\% to 15\% of cancer people.\textsuperscript{9} In children, primary brain tumors are second only to leukemia.\textsuperscript{36} The mortality rate among this age group approaches 4.5\%.\textsuperscript{37}

**Types of Tumors**

For most neoplasms, the term *malignant* is used to describe the tumor’s lack of cell differentiation, its invasive nature, and its ability to metastasize. However, the terms *benign* and *malignant* do not apply to brain tumors in the same sense as they do to tumors in other parts of the body. In the brain, even a well-differentiated and histologically benign tumor may grow and cause death because of its location. Most histologically benign tumors infiltrate the normal brain tissue, preventing total resection and allowing for tumor recurrence. Classification of brain tumors is based on histopathologic characteristics. The World Health Organization (WHO) system is the most widely used classification system for brain tumors.\textsuperscript{9,2}

Brain tumors can be divided into three basic types:

- **Primary intracranial tumors that originate in the skull cavity but are not derived from the brain tissue itself** (e.g., meninges, pituitary gland, pineal gland, primary CNS lymphoma)
- **Metastatic tumors**

Collectively, neoplasms of astrocytic origin are the most common type of primary brain tumor in adults, followed by primary CNS lymphoma.

**Glial Tumors.** Glial tumors are divided into two main categories: astrocytic and oligodendrogial. For purposes of classification, astrocytic tumors can be subdivided into fibrillary (infiltrating) astrocytomas and pilocytic astrocytomas.

Fibrillary or diffuse astrocytomas account for 80\% of adult primary brain tumors. They are most common in middle age, with the anaplastic astrocytomas having a peak incidence in the sixth decade. Although they usually are found in the cerebral hemispheres, they also can occur in the cerebellum, brain stem, or spinal cord. Astrocytomas of the cerebral hemispheres commonly are divided into three grades of increasing pathologic anaplasia and rapidity of progression: well-differentiated lesions, designated *astrocytomas*; intermediate-grade tumors, termed *anaplastic astrocytomas*; and the least differentiated and most aggressive, designated *glioblastoma multiforme*. Clinically, infiltrating astrocytic tumors present with symptoms of increased ICP (e.g., headache) or focal abnormalities related to their position (e.g., seizures).

Pilocytic astrocytomas are distinguished from other astrocytomas by their cellular appearance and their benign behavior. Typically, they occur in children and young adults and usually are located in the cerebellum, but they also can be found in the floor and walls of the third ventricle, in the optic chiasm and nerves, and occasionally in the cerebral hemispheres. The prognosis of people with pilocytic astrocytomas is influenced primarily by their location. The prognosis is usually better for people with surgically resectable tumors, such as those located in the cerebellar cortex, than for people with less accessible tumors, such as those involving the hypothalamus or brain stem.

Oligodendrogliomas are tumors of the oligodendrocytes or their precursors, or with histologic features representing both oligodendrocytes and astrocytes. They represent approximately 5\% to 20\% of glial tumors and are most common in middle life.\textsuperscript{38} The prognosis of people with oligodendrogliomas is less predictable than for persons with infiltrating astrocytomas. It depends on the histologic grade of the tumor, its location, and recognition of molecular features that can be linked to chemosensitivity.\textsuperscript{38} The oligodendroglial tumors are prone to spontaneous hemorrhage owing to their delicate vasculature.

**Ependymomas.** Ependymomas are derived from the single layer of epithelium that lines the ventricles and spinal canal. Although they can occur at any age, they are most likely to occur in the first two decades of life and most frequently affect the fourth ventricle; they constitute 8\% to 10\% of brain tumors in this age group.\textsuperscript{38} The spinal cord is the most common site for ependymomas occurring in middle age. The clinical features depend on the location of the neoplasm. Intracranial tumors are often associated with hydrocephalus and evidence of increased ICP.

**Meningiomas.** Meningiomas develop from the meningotheelial cells of the arachnoid and are outside the brain. They usually have their onset in the middle or later years of life and constitute approximately 20\% of primary brain tumors in this age group.\textsuperscript{38} Meningiomas are slow-growing, well-circumscribed, and often highly vascular tumors. They usually are benign, and complete removal is possible if the tumor does not involve vital structures.

**Primary Central Nervous System Lymphomas.** Primary CNS lymphoma has increased in incidence by a factor of 10 in the past two decades. These deep, periventricular, and diffuse tumors are especially common in immunocompromised people and are associated with the Epstein-Barr virus and derived from large B cells. Most are malignant, and recurrence is common despite treatment. Behavioral and cognitive changes, which are the most common presenting symptoms, occur in about 43\% of people. Hemiparesis, aphasia, and visual field deficits occur in about 4\% of people and seizures occur in 14\% of people.\textsuperscript{38}

**Etiology**

A few environmental risk factors can contribute to the risk of developing a brain tumor.\textsuperscript{18} High-dose irradiation increases the risk of gliomas, meningiomas, and nerve sheath tumors. Acquired immune suppression also increases the risk for primary CNS lymphoma. Other environmental risk factors and occupational exposures have not been convincingly demonstrated to increase the risk of brain tumors (e.g., head trauma, industrial exposure to polyvinyl chloride, dietary exposure to N-nitrosoareua compounds).\textsuperscript{18} Several genetic syndromes
increase the risk of brain tumors like neurofibromatosis type 1 and 2, Li-Fraumeni syndrome, tuberous sclerosis, von Hippel-Lindau syndrome, and Burkitt syndrome.18

**Clinical Manifestations**

Intracranial tumors give rise to focal disturbances in brain function and increased ICP. Focal disturbances occur because of brain compression, tumor infiltration, disturbances in blood flow, and brain edema.

Tumors may be located intra-axially (i.e., within brain tissue) or extra-axially (i.e., outside brain tissue, but within the cranium). Disturbances in brain function usually are greatest with fast-growing, infiltrative, intra-axial tumors because of compression, infiltration, and necrosis of brain tissue. Extra-axial tumors, such as meningiomas, may reach a large size without producing signs and symptoms. Cysts may form in tumors and contribute to brain compression. The clinical manifestations of brain tumors depend on the size and location of the tumor. General signs and symptoms include headache, nausea, vomiting, mental changes, papilledema, visual disturbances (e.g., diplopia), alterations in sensory and motor function, and seizures. Because the volume of the intracranial cavity is fixed, brain tumors cause a generalized increase in ICP when they reach sufficient size or produce edema. Cerebral edema usually is of the vasogenic type, which develops around the tumors and is characterized by increased brain water and expanded extracellular fluid. The edema is thought to result from increased permeability of tumor capillary endothelial cells. Tumors can also obstruct the flow of CSF in the ventricular cavities and produce hydrocephalic dilation of the proximal ventricles and atrophy of the cerebral hemispheres. With very slow-growing tumors, complete compensation of ventricular volumes can occur, but with rapidly growing tumors, increased ICP is an early sign. Depending on the location of the tumor, brain displacement and herniation of the uncus or cerebellum may occur.

Headache that accompanies brain tumors results from compression or distortion of pain-sensitive dural or vascular structures. It may be felt on the same side of the head as the tumor, but more commonly is diffuse. In the early stages, the headache is mild and occurs in the morning on awakening and improves with head elevation. The headache becomes more constant as the tumor enlarges and often is worsened by coughing, bending, or sudden movements of the head.

Vomiting occurs with or without nausea, may be projectile, and is a common symptom of increased ICP and brain stem compression. Direct stimulation of the vomiting center, which is located in the medulla, may contribute to the vomiting that occurs with brain tumors. The vomiting is often associated with headache. Papilledema (edema of the optic disk) results from increased ICP and obstruction of the CSF pathways. It is associated with decreased visual acuity, diplopia, and deficits in the visual fields. Visual defects associated with papilledema often are the reason that people with brain tumor seek medical care.

Personality and mental changes are common with brain tumors. People with brain tumors often are irritable initially and later become quiet and apathetic. They may become forgetful, seem preoccupied, and appear to be psychologically depressed. Because of the mental changes, a psychiatric consultation may be sought before a diagnosis of brain tumor is made.

Focal signs and symptoms are determined by the location of the tumor. Tumors arising in the frontal lobe may grow to large size, increase the ICP, and cause signs of generalized brain dysfunction before focal signs are recognized. Tumors that impinge on the visual system cause visual loss or visual field defects long before generalized signs develop. Certain areas of the brain have a relatively low threshold for seizure activity. Temporal lobe tumors often produce seizures as their first symptom. Hallucinations of smell or hearing and déjà vu phenomena are common focal manifestations of temporal lobe tumors. Brain stem tumors commonly produce upper and lower motor neuron signs, such as weakness of facial muscles and ocular palsies that occur with or without involvement of sensory or long motor tracts. Cerebellar tumors often cause ataxia of gait.

**Diagnosis and Treatment**

The diagnosis of brain tumors is mainly done with an MRI. Gadolinium-enhanced MRI is the test of choice for identifying and localizing the presence and extent of tumor involvement. CT scans may fail to reveal certain mass lesions such as low-grade tumors or posterior fossa masses. Diagnostic maneuvers that suggest a possible tumor and indicate the need for MRI include physical and neurologic examinations and visual field and funduscopic examination. Cerebral angiography can be used to visualize the tumor’s vascular supply, information that is important when planning surgery. MRI may be supplemented with positron emission tomography to better characterize the metabolic properties of the tumor, useful in planning treatment.18 MRA and CTA can be used to distinguish vascular masses from tumors.

The three general methods for treatment of brain tumors are surgery, irradiation, and chemotherapy. Surgery is part of the initial management of virtually all brain tumors; it establishes the diagnosis and achieves tumor removal in many cases. The development of microsurgical neuroanatomy, the operating microscope, and advanced stereotactic and ultrasonographic technology; the fusion of imaging systems with resection techniques; and the intraoperative monitoring of evoked potentials or the EEG have improved the effectiveness of surgical resection. The degree of removal may be limited by the location of the tumor and its invasiveness. Stereotactic surgery uses three-dimensional coordinates and CT and MRI to localize a brain lesion precisely. Ultrasonographic technology has been used for localizing and removing tumors. The ultrasonic aspirator, which combines a vibrating head with suction, permits atraumatic removal of tumors from cranial nerves and important cortical areas. Intraoperative monitoring of evoked potentials is an important adjunct to some types of surgery. For example, evoked potentials can be used to monitor auditory, visual, speech, or motor responses during surgery done under local anesthesia.

Most malignant brain tumors respond to external irradiation. Irradiation can increase longevity and sometimes can allay symptoms when tumors recur. The treatment dose
Chemotherapy is standard of care for high-grade gliomas. Intra-
thecally (into the spinal canal), or intraventricularly, agents can be administered intravenously, intra-arterially, as an adjunct to surgery and radiation therapy. Chemotherapeutic agents can be administered intraventricularly (i.e., into the spinal canal), or intraventricularly. Chemotherapy is standard of care for high-grade gliomas.

IN SUMMARY

Infections of the CNS may be classified according to the structures involved (e.g., menigitis, encephalitis) or the type of organism causing the infection. The damage caused by infection may predispose to hydrocephalus, seizures, or other neurologic defects.

Brain tumors account for 2% of all cancer deaths and are the second most common type of cancer in children. Brain tumors can arise primarily from intracranial structures, and tumors from other parts of the body often metastasize to the brain. Primary brain tumors can arise from any structure in the cranial cavity. Most begin in brain tissue, but the pituitary, the pineal region, and the meninges also are sites of tumor development. Brain tumors cause focal disturbances in brain function and increased ICP. Focal disturbances result from brain compression, tumor infiltration, disturbances in blood flow, and cerebral edema. The clinical manifestations of brain tumor depend on the size and location of the tumor. General signs and symptoms include headache, nausea, vomiting, mental changes, papilledema, visual disturbances, alterations in motor and sensory function, and seizures. Diagnostic tests include physical examination, visual field testing and funduscopic examination, CT scans, MRI studies, brain scans, and cerebral angiography. Treatment includes surgery, radiation therapy, and chemotherapy.

KEY POINTS

SEIZURE DISORDERS

After completing this section of the chapter, you should be able to meet the following objectives:

- Discuss the causes of seizures.
- Describe the origin of seizure activity in focal and generalized seizures and compare the manifestations of a focal seizure and generalized seizures.

A seizure represents the abnormal behavior caused by an electrical discharge from neurons in the cerebral cortex. A seizure is a discrete clinical event with associated signs and symptoms that vary according to the site of neuronal discharge in the brain. Manifestations of seizure generally include sensory, motor, autonomic, or psychic phenomena. Approximately 2 million people in the United States are subject to recurrent seizures. Seizure activity is the most common disorder encountered in pediatric neurology, and among adults its incidence is exceeded only by cerebrovascular disorders. In most people, the first seizure episode occurs before 20 years of age. After 20 years of age, a seizure is caused most often by a structural change, trauma, tumor, or stroke.

Seizures may occur during almost all serious illnesses or injuries affecting the brain, including metabolic derangements, infections, tumors, drug abuse, vascular lesions, congenital deformities, and brain injury. A seizure is a single event of abnormal discharge that results in an abrupt, altered state of cerebral function. Epilepsy is a chronic disorder of recurrent discharges from neurons. The current classification system endorsed by the International League Against Epilepsy classifies seizures into generalized and focal as occurring in and rapidly engaging bilaterally distributed networks (generalized) and within networks limited to one hemisphere and either discretely localized or more widely distributed (focal).

Etiology

Many theories have been proposed to explain the cause of the abnormal brain electrical activity that occurs with seizures. Seizures may be caused by alterations in cell membrane permeability or distribution of ions across the neuronal cell membranes. Another cause may be decreased inhibition of cortical or thalamic neuronal activity or structural changes that alter the excitability of neurons. Neurotransmitter imbalances such as an acetylcholine excess or γ-aminobutyric acid (GABA, an inhibitory neurotransmitter) deficiency have been proposed as causes. Certain epilepsy syndromes have been linked to specific genetic mutations causing ion channel defects.
Classification

The International Classification of Epileptic Seizures determines seizure type by clinical symptoms and EEG activity. It divides seizures into two broad categories:

- Focal seizures, in which the seizure begins in a specific or focal area of one cerebral hemisphere
- Generalized seizures, which begin simultaneously in both cerebral hemispheres

The system also has a category for seizures of unknown origin, such as epileptic spasms.

Focal Seizures

Focal seizures are the most common type of seizure among newly diagnosed cases. For focal seizures, the original distinctions of simple partial, complex partial, and so on have been eliminated. Instead, these seizures must be differentiated into two major groups—without impairment of consciousness or awareness and with impairment of consciousness or awareness.

Although descriptors of focal seizures may be used based on the earlier classification of seizures, the following revised descriptors of degree of impairment developed by the International League Against Epilepsy Commission on Classification and Terminology, 2005–2009, can help differentiate in the evaluation of each person who is experiencing focal seizures:

- Focal seizures without impairment of consciousness or awareness
  - Focal seizures with observable motor or autonomic components. (This roughly corresponds to the concept of “simple partial seizure.” “Focal motor” and “autonomic” are terms that may adequately convey this concept depending on the seizure manifestations.)
  - Focal seizures involving subjective sensory or psychic phenomena only (This corresponds to the concept of an aura.)

Seizures without Impairment of Consciousness or Awareness. These types of seizures usually involve only one hemisphere and are not accompanied by loss of consciousness or responsiveness. These seizures have been referred to as simple partial seizures, elementary partial seizures, partial seizures with elementary symptoms.

The observed clinical signs and symptoms depend on the area of the brain where the abnormal neuronal discharge is taking place. If the motor area of the brain is involved, the earliest symptom is motor movement corresponding to the location of onset on the contralateral side of the body. The motor movement may remain localized or may spread to other cortical areas. If the sensory portion of the brain is involved, there may be no observable clinical manifestations. Sensory symptoms correlating with the location of seizure activity on the contralateral side of the brain may involve somatic sensory disturbance (e.g., tingling and crawling sensations) or special sensory disturbance (i.e., visual, auditory, gustatory, or olfactory phenomena). When abnormal cortical discharge stimulates the autonomic nervous system, flushing, tachycardia, diaphoresis, hypotension or hypertension, or pupillary changes may be evident.

The term prodrome or aura traditionally has meant a stereotyped warning sign of impending seizure activity described by the affected person. The aura actually represents a simple partial seizure, reflecting only a small area of abnormal electrical activity in the brain. Simple partial seizures may progress to complex partial seizures or generalized tonic–clonic seizures that result in unconsciousness. Most people perceive the aura as a warning sign of impending complex partial seizures or other generalized seizures.

Seizures with Impairment of Consciousness or Awareness. These types of seizures involve impairment of consciousness and often arise from the temporal lobe. The seizure begins in a localized area of the brain but may progress rapidly to involve both hemispheres. These seizures are sometimes referred to as psychomotor seizures, reflecting their typical manifestations.

These types of seizures often are accompanied by automatisms. Automatisms are repetitive, nonpurposeful activities such as lip smacking, grimacing, patting, or rubbing clothing. Confusion during the postictal state (after a seizure) is common. Hallucinations and illusional experiences such as déjà vu (familiarity with unfamiliar events or environments) or jamais vu (unfamiliarity with a known environment) have been reported. There may be overwhelming fear, uncontrolled forced thinking or a flood of ideas, and feelings of detachment.
Absence seizures. Phases last approximately 60 to 90 seconds. This motion takes the form of automatisms such as lip smacking, mild clonic motion (usually in the eyelids), increased or decreased postural tone, and autonomic phenomena. There often is a brief loss of contact with the environment. The seizure usually lasts only a few seconds, and then the person is able to resume normal activity immediately. The manifestations often are so subtle that they may pass unnoticed. Because automatisms and unresponsiveness are common to complex partial seizures, the latter often are mistakenly labeled as “petit mal” seizures.

Atypical absence seizures are similar to typical absence seizures except for greater alterations in muscle tone and less abrupt onset and cessation. In practice, it is difficult to distinguish typical from atypical absence seizures without the benefit of supporting EEG findings. However, it is important to distinguish between focal seizures with impairment of consciousness or awareness and absence seizures because the drugs of choice for treatment are different. Medications that are effective for focal seizures may increase the frequency of absence seizures.

Myoclonic seizures. Myoclonic seizures involve brief involuntary muscle contractions induced by stimuli of cerebral origin. A myoclonic seizure involves bilateral jerking of muscles, generalized or confined to the face, trunk, or one or more extremities.

Clonic seizures. Clonic seizures begin with a loss of consciousness and sudden hypotonia. This is followed by limb jerking that may or not be symmetrical.

Tonic seizures. In a tonic seizure there is a sudden onset of increased tone, which is maintained in the extensor muscles. It is often associated with falling.

Atonic seizures. In atonic seizures, there is a sudden, split-second loss of muscle tone leading to slackening of the jaw, drooping of the limbs, or falling to the ground. These seizures also are known as drop attacks.

Diagnosis and Treatment

The diagnosis of seizure disorders is based on a thorough history and neurologic examination, including a full description of the seizure. The physical examination and laboratory studies help exclude any metabolic disease (e.g., hyponatremia) that could precipitate seizures. MRI scans are used to identify structural defects such as temporal lobe sclerosis or underlying congenital malformations causing the seizure. One of the most useful diagnostic tests is the EEG, which is used to record changes in the brain’s electrical activity. It is used to support the clinical diagnosis of epilepsy, to provide a guide for prognosis, and to assist in classifying the seizure disorder.

The first rules of treatment are to protect the person from injury during a seizure, preserve brain function by aborting or preventing seizure activity, and treat any underlying disease.
People with epilepsy should be advised to avoid situations that could be dangerous or life-threatening if seizures occur. Treatment of the underlying disorder may reduce the frequency of seizures.

After the underlying disease is treated, the aim of treatment is to bring the seizures under control with the least possible disruption in lifestyle and minimum side effects from medication. Since the late 1970s, the therapy for epilepsy has changed drastically because of an improved classification system, the ability to measure serum anticonvulsant levels, and the availability of potent new anticonvulsant drugs. With proper drug management, 60% to 80% of people with epilepsy can obtain good seizure control.40

**Anticonvulsant Medications**

Until 1990, approximately 16 antiseizure drugs were available including carbamazepine, phenytoin, ethosuximide, valproic acid, phenobarbital, primidone, and clonazepam.41 Newer antiepileptic drugs that have been marketed since 1996 include gabapentin, lamotrigine, felbamate, topiramate, levetiracetam, tiagabine, oxcarbazepine, and vigabatrin.41

Choice of drugs used as first-line therapy for seizure disorders has changed since the newer drugs were introduced because they have much better side effect profiles.7 Carbamazepine, gabapentin, lamotrigine, levetiracetam, oxcarbazepine, topiramate, valproic acid, and zonisamide are the drugs of choice in treating focal seizures or tonic–clonic seizures resulting from focal seizures. Ethosuximide or valproic acid is the drug of choice for absence seizures. Valproic acid, carbamazepine, oxcarbazepine, and lamotrigine are helpful for people with many of the minor motor seizures and tonic–clonic seizures. Myoclonic seizures can be treated with valproic acid. Atonic seizures are highly resistant to therapy. Each of the new drugs—gabapentin, lamotrigine, topiramate, and oxcarbazepine—is approved for use as monotherapy in adults who have focal seizures alone or with secondarily generalized (grand mal) seizures. The other agents are approved as add-on therapy when the first-line agent is not fully effective. In all cases, side effect profiles and patient-specific factors affect choice of antiepileptic medications.

Women of childbearing age require special consideration concerning fertility, contraception, and pregnancy. Many of the drugs interact with oral contraceptives; some affect hormone function or decrease fertility. All such women should be advised to take folic acid supplementation. For women with epilepsy who become pregnant, antiseizure drugs increase the risk for congenital abnormalities and other perinatal complications. Carbamazepine, phenytoin, phenobarbital, primidone, and valproic acid can interfere with vitamin D metabolism and predispose to osteoporosis.

Whenever possible, a single drug should be used in epilepsy therapy. Monotherapy eliminates drug interactions and additive side effects. Determining the proper dose of the anticonvulsant drug is often a long and tedious process, which can be very frustrating for the person with epilepsy. Consistency in taking the medication is essential. Anticonvulsant drugs never should be discontinued abruptly. The dose should be decreased slowly to prevent seizure recurrence. The most frequent cause of recurrent seizures is patient noncompliance with drug regimens. Ongoing education and support are extremely important in the management of seizures. The psychosocial implications of a diagnosis of epilepsy continue to have a large impact on those affected with the disorder.

The neurologist and primary care physician must work together when a person on anticonvulsant medication becomes ill and must take additional medications. Some drugs act synergistically, and others interfere with the actions of anticonvulsant medications. This situation needs to be carefully monitored to avoid overmedication or interference with successful seizure control.

**Surgical Therapy**

Surgical treatment may be an option for people with epilepsy that is refractory to drug treatment.42 With the use of modern neuroimaging and surgical techniques, a single epileptogenic lesion can be identified and removed without leaving a neurologic deficit. The most common surgery consists of removal of the amygdala and an anterior part of the hippocampus and entorhinal cortex, as well as a small part of the temporal pole, leaving the lateral temporal neocortex intact. Another surgical procedure involves partial removal of the corpus callosum to prevent spread of a unilateral seizure to a generalized seizure. Some refractory patients benefit from an implantable electrical stimulator of the vagus nerve. Modern epilepsy surgery requires a multidisciplinary team of highly skilled surgeons and specialists working together in an epilepsy center. Most procedures require only a few hours in the operating room and a few days’ stay in the hospital after surgery. Epilepsy surgery is increasingly considered a treatment modality for persons with medically intractable epilepsy.

**Status Epilepticus**

Seizures that do not stop spontaneously or occur in succession without recovery are called status epilepticus. Status epilepticus is a medical emergency and, if not promptly treated, may lead to respiratory failure and death.

The disorder occurs most frequently in the young and old. Morbidity and mortality rates are highest in older adults and people with acute symptomatic seizures, such as those related to anoxia or cerebral infarction.43 Approximately one third of people have no history of a seizure disorder, and in another one third, status epilepticus occurs as an initial manifestation of epilepsy.43 If status epilepticus is caused by neurologic or systemic disease, the cause needs to be identified and treated immediately because the seizures probably will not respond until the underlying cause has been corrected.

Treatment consists of appropriate life support measures. Medications are given to control seizure activity. Intravenously administered diazepam or lorazepam is considered first-line therapy for the condition. The prognosis is related to the underlying cause as well as the duration of the seizures themselves.
Nonconvulsive seizures (NCS) are common in the person in intensive care unit (ICU). At least 8% of comatose people in a general ICU have NCS. The prevalence of NCS is about 48% of people who remain comatose after a generalized seizure. It occurs in at least 20% of people with acute structural brain lesions (e.g., traumatic injury). NCS cannot be detected without continuous EEG monitoring. People who are comatose require 48 hours of continuous EEG recording to detect seizure activity. Seizure duration is strongly associated with outcome.44

In Summary

Seizures are caused by spontaneous, uncontrolled, paradoxical, transitory discharges from cortical centers in the brain. Seizures may occur as a reversible symptom of another disease condition or as a recurrent condition called epilepsy. Epileptic seizures are classified as focal or generalized seizures. Focal seizures have evidence of local onset, beginning in one hemisphere. Generalized seizures involve both hemispheres from the start and include unconsciousness and rapidly occurring, widespread, bilateral symmetric motor responses. They include minor motor seizures such as absence and akinetic seizures, and major motor or grand mal seizures. Control of seizures is the primary goal of treatment and is accomplished with anticonvulsant medications. Anticonvulsant medications interact with each other and need to be monitored closely when more than one drug is used. Status epilepticus is a medical emergency and, if not promptly treated, may lead to respiratory failure and death. NCS are common in the person in ICU and cannot be detected without continuous EEG monitoring.

Review Exercises

1. A 20-year-old man is an unbelted driver involved in a motor vehicle crash and presents in a coma.
   A. What are the clinical signs of coma?
   B. Where does the source of coma localize in the brain?
   C. Which complications of traumatic brain injury might lead to coma?
   D. What are the key treatment options to manage increased intracranial pressure?

2. A 65-year-old woman presents with a 1-hour history of right-sided facial droop, arm weakness, and dysarthria. An immediate CT scan of the brain is negative.
   A. Where in the brain is the pathologic process?
   B. What are the indications to administer intravenous tissue plasminogen activator?
   C. What are the possible causes of this stroke, and what diagnostic tests would reveal the cause?

3. A child is taken to the emergency department with lethargy, fever, and a stiff neck on examination.
   A. What findings on initial lumbar puncture indicate bacterial versus viral meningitis?
   B. In the case of bacterial meningitis, what are the most likely organisms?
   C. If he has a long history of similar recurrent seizures, what treatments should be instituted? What treatments should be considered if he has failed multiple adequate trials of anticonvulsant medications?

As humans, we spend approximately a third of our lives asleep. We all know what sleep feels like. Yet defining sleep, describing what happens when we sleep, and explaining why we sleep are more difficult. Of equal concern is an understanding of factors that interfere with sleep. For many people, the inability to engage in appropriate periods of normal, restful sleep seriously impairs their functioning. The content in this chapter is divided into three parts:

1. The neurobiology of sleep
2. Sleep disorders
3. Sleep and sleep disorders in children and older adults

NEUROBIOLOGY OF SLEEP

As humans, we spend approximately a third of our lives asleep. We all know what sleep feels like. Yet defining sleep, describing what happens when we sleep, and explaining why we sleep are more difficult. Of equal concern is an understanding of factors that interfere with sleep. For many people, the inability to engage in appropriate periods of normal, restful sleep seriously impairs their functioning. The content in this chapter is divided into three parts:

1. The neurobiology of sleep
2. Sleep disorders
3. Sleep and sleep disorders in children and older adults

Sleep is part of what is called the sleep–wake cycle. In contrast to wakefulness, which is a time of mental activity and energy expenditure, sleep is a period of inactivity and restoration of mental and physical function. It has been suggested that sleep provides time for entering information that has been acquired during periods of wakefulness into memory and for reestablishing communication between various parts of the brain. Sleep also is a time when other body systems restore their energy and repair their tissues. Muscle activity and digestion decrease, and sympathetic nervous system activity is diminished. Many hormones, such as growth hormone, are produced in a cyclic manner correlating with the
sleep–wake cycle, suggesting that growth and tissue repair may occur during sleep.

**Neural Structures and Pathways**

Anatomically, the sleep–wake cycle involves structures in the thalamus, associated areas of the cerebral cortex, and interneurons in the reticular formation of the midbrain, pons, and brain stem (Fig. 21.1A). The reticular formation of the midbrain, pons, and brain stem monitors and modulates the activity of various circuits controlling wakefulness. The thalamus and the cerebral cortex function in tandem, with all sensory information being relayed to the thalamus and from there to the cerebral cortex. For example, visual impulses from the retina go to the thalamus and are then relayed to the visual cortex. The pathways between each sensory area of the thalamus and the cortex form two-way communication loops called thalamocortical loops. Communication between each sensory area of the thalamus and its companion area in the cortex is kept orderly by several neuronal control systems, including the midbrain reticular formation that controls the level of background activity so that external stimuli can be processed.

**The Sleep–Wake Cycle**

The sleep–wake cycle normally consists of a synchronous pattern of wakefulness and sleep. Wakefulness is a state of being aware of the environment—of receiving and responding to information arriving from all the senses, placing that information into memory, and recalling and integrating present experiences with previously stored memories. During wakefulness, both the thalamocortical loop and brain stem centers are active. A full repertoire of motor movements is made possible by corticospinal circuits that travel through the brain stem. Sleep represents a period of diminished consciousness from which a person can be aroused by sensory or other stimuli. It occurs in stages during which the brain remains active, but does not effectively process sensory information. However, during sleep, a person does have inward conscious experiences such as dreams.

**Brain Waves**

Many of the advances in understanding the sleep–wake cycle have come about because of the ability to record brain waves through the use of the electroencephalogram (EEG). The source of the brain waves is the alternating excitatory and inhibitory nerve activity in postsynaptic potentials in cortical neurons. During the recording of an EEG, the postsynaptic potentials are averaged and filtered to improve the quality of the signal. As such, the EEG does not measure the activity of a single neuron, but rather the combined activity and “cross talk” among many hundreds of neurons responding to a given stimulus.

The normal EEG consists of brain waves of various frequencies (measured in cycles per second, or hertz [Hz]) and
Chapter 21  Sleep and Sleep Disorders

Sleep Stages

There are two types of sleep: rapid eye movement (REM) and non–rapid eye movement (NREM) sleep. These two types of sleep alternate with each other and are characterized by differences in eye movements, muscle tone and body movements, heart rate and blood pressure (BP), breathing patterns, brain wave activity, and dreaming (Table 21.1). A complete sleep cycle takes about 90 to 110 minutes.

Non–Rapid Eye Movement Sleep. NREM sleep, or slow-wave sleep, is a quiet type of sleep characterized by a relatively inactive, yet fully regulating brain and a fully movable body. It accounts for 80% to 85% of sleep. The brain stem coordinates activity between the spinal cord and various reflexes such as swallowing and chewing. NREM sleep normally is encountered when the person first becomes drowsy. Falling asleep does not occur all at once. It is divided into four stages that reflect an increasing depth of sleep (Fig. 21.3):

- Stage 1
- Stage 2
- Stage 3
- Stage 4

Stage 1 consists of low-voltage, mixed-frequency, alpha wave EEG activity. It occurs at sleep onset and is a brief (1 to 7 minutes) transitional stage between wakefulness and true sleep. During this stage, people can be easily aroused simply by touching them, calling their name, or quietly closing a door. People may experience sudden muscle contractions called hypnic myoclonia, similar to a “jump” we may experience when we are startled. Oftentimes these contractions are preceded by a sensation of falling. In addition to its role at sleep onset, stage 1 serves as a transitional stage for repeated sleep cycles throughout the night. During the first third of sleeping, stage 1 is usually shorter and the longest during the last third of sleeping. A common sign of

memories and existing neocortical knowledge. A more intense stimulus is required for arousal in this stage.

Stages 3 and 4 represent deep sleep and are dominated by high-voltage, low-frequency (0.5 to 4 Hz) delta waves. Stage 3 usually lasts only a few minutes and is transitional to stage 4, which lasts for approximately 20 to 40 minutes in the first cycle. An increasingly larger stimulus is required for arousal from stage 3 to stage 4. During deep sleep, the muscles of the body relax and posture is adjusted intermittently. The heart rate and BP decrease, and gastrointestinal activity is slowed.

Rapid Eye Movement Sleep. REM sleep is associated with rapid eye movements, loss of muscle movements, and vivid dreaming. The brain is highly active during REM sleep, and it accounts for 20% to 25% of sleep. External sensory input is inhibited, whereas internal sensory circuits such as those of the auditory and visual systems are aroused. During this time, the brain can replay previous memories but cannot acquire new sensory information (Fig. 21.4). At the same time, motor systems that control body movements are inhibited. There is a loss of muscle movement and muscle tone. The result is an extraordinary set of paradoxes, in which people see things in their dreams, but cannot move. They imagine being engaged in activities such as running, flying, or dancing but are paralyzed.
There also are changes in autonomic nervous system–controlled functions during REM sleep—BP, heart rate, and respirations increase and fluctuate and temperature regulation is lost. Cerebral blood flow and metabolic rate decrease. The brain is highly active and brain metabolism may increase as much as 20%.1 Sleep-related penile erection occurs during this stage of sleep.

It has been shown that adequate amounts of REM sleep are necessary for normal daytime functioning. Deprivation of REM sleep is associated with anxiety, irritability, inability to concentrate, and, if deprivation is severe enough, disturbed behavior.

Moving Between Sleep Stages. There is a rather predictable pattern of shifting between one NREM stage and another during a typical night’s sleep.2,3,5 At sleep onset, there is a stepwise descent from lighter stage 1 sleep to deeper stage 4 sleep, followed by an abrupt ascent back toward stage 1. However, in place of stage 1, the first REM episode usually occurs. REM sleep is comparatively short (1 to 5 minutes) during the first sleep cycle, but gradually becomes longer across the night. Stages 3 and 4 occupy less time in the second and subsequent sleep cycles and disappear altogether in later cycles as stage 2 expands to occupy the NREM sleep cycle. By morning, nearly all of the sleep cycle is spent in stages 1, 2, and REM.3 People typically awake spontaneously in the morning while in an episode of REM sleep.1

Breathing During Sleep
Breathing normally changes during sleep. Stages 1 and 2 of NREM sleep are characterized by a cyclic waning and waxing of the tidal volume and respiratory rate, which may include brief periods (5 to 15 seconds) of apnea. After sleep has stabilized during stages 3 and 4 of NREM sleep, breathing becomes more regular. Ventilation usually is 1 to 2 L/minute less than during quiet wakefulness, the arterial carbon dioxide partial pressure (PCO₂) is 2 to 4 mm Hg greater, and the arterial oxygen partial pressure (PO₂) is 3 to 9 mm Hg less.7 Involuntary respiratory control mechanisms, such as responses to hypercapnia, hypoxia, and lung inflation, are intact during NREM sleep and critically important to maintaining ventilation.

During REM sleep, respirations become irregular, but not periodic, and may include short periods of apnea. Breathing during REM sleep has many features of the voluntary control that integrates breathing with acts such as walking, talking, and swallowing. However, their influence on breathing is diminished.

Dreaming
Dreams are recollections of mental activity that occurred during sleep. They occur during all stages of sleep, but the majority of dreams occur during REM and sleep onset (stages 1 and 2).2 Dreams that occur during REM sleep tend to be bizarre and colorful. Most nightmares occur during stages 3 and 4.2 Dreams that occur during stages 1 and 2 of sleep tend to be shorter, have fewer associations, and lack the color and emotion of those that occur during REM sleep.

The purpose of dreaming is unclear. Evidence suggests that dreaming, like other physiologic functions, is important to learning and memory processing. It has been suggested that dreaming may be the result of reprogramming of the central nervous system (CNS; i.e., rearranging previous experiences) in preparation for the next day’s conscious experiences.

KEY POINTS

SLEEP–WAKE CYCLE

- The sleep–wake cycle normally consists of a synchronous pattern of wakefulness and sleep. Wakefulness is a state of being aware of the environment, receiving and responding to sensory input, recalling and integrating experiences into memory, and purposeful body movements.
- Sleep, which is a period of inactivity and restoration of mental and physical function, is characterized by alternations between NREM (slow-wave sleep) and REM (paradoxical sleep).2

Circadian Rhythms

Normally, sleep and wakefulness occur in a cyclic manner, integrated into the 24-hour light–dark solar day. The term circadian, from the Latin circa (“about”) and dies (“day”), is used to describe these 24-hour diurnal rhythms. The function of the circadian time system is to provide a temporal organization for physiologic processes and behaviors as a means of promoting effective adaptation to the environment. At the behavioral level, this is expressed in regular cycles of sleep and waking and body functions such as temperature regulation and hormone secretion based on changes in the 24-hour light–dark solar day.

The daily rhythm of the sleep–wake cycle is part of a timekeeping system created by an internal pacemaker or clock.2,3,5,8 The light/dark environment that accounts for the circadian rhythm involves a widely distributed network in the brain and the periphery.3,8 Because the intrinsic sleep–wake cycle tends to be longer than 24 hours, a daily resetting of the circadian clock is necessary to synchronize with the environmental day. This process is called entrainment and normally is accomplished by exposure to the light–dark changes of the solar day.

The circadian clock appears to be controlled by a small group of hypothalamic cells, called the suprachiasmatic nucleus (SCN), located just above the optic chiasm and lateral to the third ventricle2,3,8 (see Fig. 21.1). The SCN, which receives light–dark input from the retina, exhibits a rhythm of neuronal firing that is high during the day and
low during the night. Although light serves as the primary stimulus for resetting the circadian clock via the SCN, other stimuli such as locomotion and activity, food availability, glucocorticoid level, and temperature are able to reset the peripheral clock. The major projections from the SCN are to the anterior pituitary, with lesser ones to the basal forebrain and midline thalamus. Projections to the anterior pituitary provide for diurnal regulation of growth hormone and cortisol secretion; those to hypothalamic centers, for changes in metabolism and body temperature; and those to the brain stem reticular formation, for changes in autonomic nervous system–regulated functions such as heart rate and BP (Fig. 21.5).

**Melatonin**

Melatonin, a hormone produced by the pineal gland, is thought to help regulate the sleep–wake cycle and, possibly, circadian rhythm. The pineal gland synthesizes and releases melatonin at night, a rhythm that is under direct control of the SCN (see Fig. 21.1). Large numbers of melatonin receptors are present in the SCN, suggesting a feedback loop between the SCN and the pineal gland. Administration of melatonin produces phase-shifting changes in the circadian rhythm, similar to those caused by light. There has been recent interest in the use of melatonin in treatment of various sleep disorders, particularly those related to a shift in the circadian rhythm. Although synthetic preparations are available without prescription in health food stores and pharmacies, their potency, purity, safety, and effectiveness cannot be ensured. Melatonin is not regulated by the Food and Drug Administration. There is also a lack of clinical trial evidence about appropriate dosage, adverse effects, drug interactions, and the effects of melatonin on various disease states. For short-term usage, MT is thought to be safe. A pharmacologic melatonin receptor agonist, ramelteon (Rozerem), is available also as a prescription drug (to be discussed).

**IN SUMMARY**

Sleep is part of what is called the *sleep–wake cycle*. In contrast to wakefulness, which is a time of mental activity and energy expenditure, sleep is a period of inactivity and restoration of mental and physical function. There are two types of sleep: REM and NREM sleep. REM sleep is associated with rapid eye movements, loss of muscle movements, and vivid dreaming. External sensory input is inhibited, whereas internal sensory circuits such as those of the auditory and visual systems are aroused. NREM sleep is a quiet type of sleep characterized by a relatively inactive, yet fully regulating brain, and a fully movable body. It is divided into four stages that reflect an increasing depth of sleep. Stage 1 is a brief transitional stage that occurs at the onset of sleep, during which a person is easily aroused. Stage 2 is a deeper sleep, lasting approximately 10 to 25 minutes, during which EEG activity is interrupted by sleep spindles consisting of bursts of high-frequency waves. Stages 3 and 4 represent deep sleep, during which the muscles of the body relax, the heart rate and BP decrease, and gastrointestinal activity is slowed.

Normally, sleep and wakefulness occur in a cyclic manner, called the *circadian rhythm*, that is integrated into the 24-hour light–dark solar day. The circadian clock is thought to be controlled by the SCN in the hypothalamus. The SCN, which receives light–dark input from the retina, exhibits a rhythm of neuronal firing that is high during the day and low during the night. Melatonin, a hormone produced by the pineal gland, is thought to help regulate the sleep–wake cycle.
SLEEP DISORDERS

After completing this section of the chapter, you should be able to meet the following objectives:

- Characterize the free-running sleep disorder experienced by visually impaired individuals, sleep disorders associated with acute shifts in the sleep–wake cycle due to intercontinental travel and shift work, and advanced sleep phase and delayed sleep phase circadian rhythm sleep disorders.
- Explain the physiologic mechanisms, contributing factors, and manifestations of obstructive sleep apnea and describe the methods used in diagnosis and treatment of the disorder.

Sleep disorders cover a broad spectrum of symptoms including the inability to fall asleep and stay asleep, circadian rhythm and sleep–wake transition disorders, sleep-related breathing and movement disorders, and excessive sleepiness. While sleep disorders have existed for centuries, it is only within the last three to four decades that attention has focused on their diagnosis and classification. The development of the Diagnostic Classification of Sleep and Arousal Disorders by the Association of Sleep Disorders in 1979 heralded the emergence of the discipline of sleep medicine. This was followed by the International Classification of Sleep Disorders (ICSD), which was produced by the American Academy of Sleep Medicine, in association with the European Sleep Research Society, the Japanese Society of Sleep Research, and the Latin American Sleep Society. First produced in 1990, the ICSD was revised in 1997 and again in 2005 as ICSD-2.11 ICSD-2 classifies sleep disorders into eight major categories (Chart 21.1).

CHART 21.1 INTERNATIONAL CLASSIFICATION OF SLEEP DISORDERS

- Insomnia
- Sleep-related breathing disorders
- Hypersomnia of central origin not due to sleep-related breathing disorder, circadian rhythm disorder, or other causes of disturbed nocturnal sleep
- Circadian rhythm sleep disorders
- Parasomnias
- Sleep-related movement disorders
- Isolated symptoms, apparently related to normal variants and unresolved issues
- Other sleep disorders

Chapter 21  Sleep and Sleep Disorders  531

Diagnostic Methods

The diagnosis of sleep disorders usually is based on an adequate sleep history and physical examination. A sleep diary or sleep log often is helpful in describing sleep problems and arriving at a diagnosis.12 In some cases, sleep laboratory studies may be needed to arrive at an accurate diagnosis.

Sleep History

A sleep history is fundamental to the process of identifying the nature of a sleep disorder.12 The history should include the person’s perception of the sleep problem, sleep schedule (e.g., times of retiring and arising), problems with falling asleep and maintaining sleep, quality of sleep, daytime sleepiness and impact of the sleep disorder on daytime functioning, general emotional and physical problems, sleep hygiene (e.g., eating and drinking before retiring), and sleep environment (e.g., bed comfort, room temperature, noise, light). Because drugs such as over-the-counter medications, herbal preparations, and prescription medications can influence sleep, a careful drug history is important. It also is important to obtain information about the use of alcohol, caffeine, tobacco, and illegal substances.

Sleep Log/Diary

A sleep log/diary is a person’s written account of his or her sleep experience. It usually is recommended that the diary be kept for at least 2 weeks. The diary should record the person’s account of their bedtime, wake-up time, total sleep time, time of sleep onset, time needed to prepare for bed and to fall asleep, use of sleep medications, number of awakenings, subjective assessment of sleep quality, time out of bed in the morning, and daytime naps and symptoms. A number of sample forms are available to health care professionals for distribution to their clients.

Actigraphy and Polysomnography

Actigraphy. Actigraphy measures muscle motion and is the most appropriate measure for obtaining objective measurements of sleep duration and efficiency outside the sleep laboratory.13,14 The actigraph is a compact device that is worn on the wrist or ankle to measure body movement, which is an indirect indicator of wakefulness and sleep. Depending on the unit that is used, it can collect up to several week’s worth of information.

Polysomnography. A typical sleep study, or polysomnography (PSG), involves the use of the EEG, electrooculogram (EOG), electromyogram (EMG), electrocardiogram (ECG), breathing movements, and pulse oximetry.13 The EOG records eye movements. Because the eye is like a small battery with the retina negative to the cornea, an electrode placed on the skin near the eye records changes in voltage as the eye rotates in its socket. The EMG records the electrical activity from muscle movement. It is recorded from the
Circadian Rhythm Disorders

Circadian sleep disorders are “sleep disorders where there is a mismatch between circadian rhythms and required sleep–wake cycle.” Sleep problems due to alternations in circadian rhythms are related to intrinsic factors (free-running disorder, irregular sleep–wake rhythm [ISWR], advanced sleep phase disorder, and delayed sleep phase disorder) and acute shifts in the sleep–wake cycle (jet lag and shift work).16

**Delayed and Advanced Sleep Phase Syndrome**

Change in sleep phase disorders include delayed sleep phase syndrome (DSPS) and advanced sleep phase syndrome (ASPS). The disorders may arise because of developmental changes in the sleep–wake cycle or because of poor sleep habits.

The main symptoms of delayed sleep phase syndrome (DSPS) are extreme difficulty falling asleep at a conventional hour of the night and awakening on time in the morning for school, work, or other responsibilities. In adults, there is evidence of association between some psychopathologic disorders and DSPS.16 DSPS is most common in adolescents whose frustrated parents cannot wake them up in time for school and have trouble getting them to go to bed at night. Staying up late is fairly common among today’s teenagers, who are strongly influenced by peer pressure, defiance of parental rules, and other pressures. It has been suggested that social pressure may contribute to, but may not be the only reason for, changes in a teenager’s sleep pattern. Rather, puberty may be accompanied by a lengthening of the intrinsic circadian rhythm, with a corresponding increase in evening wakefulness, which in turn leads to later sleep onset and arising.

Diagnosis of DSPS is usually made from information in a sleep history, confirmed with a 2-week sleep log or diary. The presence of concurrent psychopathologic disorders or chronic sedative or alcohol use should be considered. There are no quick remedies for DSPS. In adolescents, commonsense remedies such as setting earlier bedtimes and using multiple alarm clocks for waking up have been used, but with minimal success. The use of bright light may be helpful in maintaining morning wakefulness.16 Treatments such as chronotherapy, scheduled bright light therapy, and the use of melatonin, hypnotics, and stimulants have been studied but provide insufficient evidence.19

Advanced sleep phase syndrome (ASPS) is essentially the mirror image of DSPS—early sleep onset and early arising. People with ASPS have trouble staying awake in the evening and have to curtail evening activities to avoid falling asleep. The pathophysiologic basis of ASPS is presumed to be a partial defect in phase delay capability, with the possibility that people with the disorder have an inherently fast circadian timing system. This disorder often occurs in older adults. Time isolation studies in middle-aged and older subjects suggest that the circadian timing system shortens with aging, usually beginning sometime in the sixth decade of life.17 Diagnosis of ASPS is based on history and information from a sleep diary. Other pathologic causes, such as sleep apnea and depression, should be ruled out. The need for treatment depends on how disruptive a person perceives the problem to be. Current treatment methods, which focus largely on sleep schedule changes, are somewhat limited.

**Acute Shifts in the Sleep–Wake Cycle**

The normal diurnal clock is set for a 24-hour day and resists changes in its pattern by as little as 1 to 2 hours/day. This means that there is a limited range of day lengths to which
humans can synchronize. Imposed sleep–wake schedules of less than 23 hours or more than approximately 26 hours, such as those that occur with intercontinental jet travel and switches in the work shift, produce increasing sleep difficulties.

**Time Zone Change (Jet Lag) Syndrome.** Jet lag, a popular term for symptoms of sleep disturbance that occur with air travel that crosses several time zones, is caused by the sudden loss of synchrony between a traveler’s intrinsic circadian clock and the local time of the flight’s destination. The severity and duration of symptoms vary depending on the number of times zones crossed, direction of travel (eastward versus westward), takeoff and arrival times, and age. Most people who cross three or four time zones experience some sleep disturbance, usually lasting two to four nights.

Circadian rhythms take longer to resynchronize to local time after eastward flights than westward flights, presumably because of the longer-than-24–hour intrinsic circadian period in most people. There is a natural tendency for the circadian clock to move later each day, making it more difficult to phase advance than to phase delay. Eastward travel requires a phase advance, wherein bedtime occurs sooner than the person’s internal clock is ready for sleep. Because the human time system seems to be less flexible in adjusting to sudden time changes after 35 years of age, age also affects adjustment to time zone changes.

Manifestations of jet lag syndrome include insomnia, daytime sleepiness, and decreased alertness and performance. Other symptoms, such as eye and nasal irritation, headache, abdominal distention, dependent edema, and intermittent dizziness, result from cabin conditions and usually remit sooner than symptoms of jet lag. Frequent travelers, such as airline personnel and business travelers, may develop chronic sleep disturbances accompanied by malaise, irritability, and performance impairment. Jet lag usually is milder in infrequent travelers, but may reduce the enjoyment of a vacation or effectiveness of business transactions. People with preexisting sleep disorders such as sleep apnea often experience a worsening of symptoms with jet travel.

Management of jet lag focuses on efforts either to maintain the home time schedule or to adapt to the new time zone schedule. For people crossing four or fewer time zones for only a few days, trying to maintain a schedule that is nearer to the home time schedule may be helpful, especially with eastward travel. For longer stays, adapting to the new time schedule as quickly as possible is probably a better strategy. Use of artificial light may enhance the adjustment to the time shift. Some studies have shown the symptoms of jet lag may be minimized with scheduled use of artificial light and adjustment of the sleep schedule prior to travel.

**Shift Work Sleep Disorder.** Shift work sleep disorder (SWSD) includes excessive sleepiness and insomnia due to a work schedule that requires wakefulness during the worker’s intrinsic sleep time. Shift work usually creates an environment in which some circadian clock–setting cues (e.g., artificial light and rest–activity) are shifted, whereas others (e.g., natural light–dark schedule, family and social routines) are not. This situation almost never allows for a complete shift of the circadian system. To complicate the situation, most night-shift workers revert to a nighttime sleeping schedule on days off. The effect of abruptly attempting to sleep at normal hours after working nights and sleeping days is biologically equivalent to a 6- to 10-hour eastbound jet flight.

Manifestations of sleep disorders of night-shift workers include shortened and interrupted daytime sleep after the night shift, somnolence and napping at work, sleepiness while commuting home, and insomnia on the nights off from work. The abrupt transitions required of workers and interruptions that occur from sleeping during the day hours naturally result in a degree of sleep deprivation. Arriving at a sleep schedule that is most supportive of the worker’s intrinsic circadian rhythm often is difficult for night-shift workers. Beginning sleep at noon rather than earlier in the morning may produce a more normal sleep period in relation to shift onset, but exacerbate insomnia on nights off. Sleeping in absolute darkness during daytime by using blackout shades or eye masks may benefit the night worker’s sleep.

**Insomnia**

Insomnia is the most common sleep disorder that affects the general population. It has been defined as three or more of the following:

- Difficulty initiating sleep
- Difficulty maintaining sleep
- Waking up too early
- Sleep that is chronically nonrestorative or poor in quality

To be classified as insomnia, these symptoms must be accompanied by at least one of the following forms of daytime impairment: fatigue or daytime sleepiness, impairment of attention, concentration, or memory; poor social, occupational, or academic performance; mood disturbance or irritability; proneness to errors or accidents at work or while driving; tension headaches or gastrointestinal distress due to sleep loss; or worries about sleep.

Primary insomnia is sleep difficulty in which other causes of sleep disruption have been ruled out or treated, whereas secondary insomnia, also called comorbid insomnia, is associated with medical conditions (e.g., chronic pain), psychiatric disorders (e.g., anxiety, depression, bipolar disorder), neurologic disorders (e.g., Parkinson disease), primary sleep disorders (e.g., sleep apnea, restless legs syndrome [RLS]), and drugs.

Estimates of the prevalence of insomnia vary depending on the method used in the diagnosis and monitoring of the condition. According to the fourth edition of the *Diagnostic and Statistical Manual of Mental Disorders*, 30% to 45% of adults in the United States have intermittent insomnia. An estimated 10% to 15% of adults have chronic insomnia.
Chronic insomnia is more common in women, especially in the postmenopausal years; in older adults, perhaps as a consequence of declining health and institutionalization; and in people with psychological and other disease conditions.

**Adjustment or Acute Insomnia**

Adjustment or acute insomnia is characterized by short periods (days or weeks) of sleep difficulty that is expected to resolve with either adaptation or resolution of the stressor. Acute insomnia often is caused by emotional and physical discomfort. Some common examples include an unfamiliar or nonconducive sleep environment, stress-related events, and sleep schedule problems. Probably one of the most common causes of acute insomnia is an unfamiliar sleep environment, such as that encountered when traveling.

Factors that contribute to a nonconducive sleep environment include excessive noise, extremes of temperature, an uncomfortable sleep surface, or being forced to sleep in an uncomfortable position. Hospital intensive care units with their noise, intensive lighting, and frequent interruptions for monitoring vital signs and providing treatments are excellent examples of nonconducive sleep environments. Common stress-related causes of insomnia are expected occurrences such as being on call or stressful life events. Sleep schedule changes include jet lag and sleep disruption due to shift work.

**Chronic Insomnia**

Chronic insomnia should be distinguished from acute insomnia. Accordingly, the National Institutes of Health (NIH) State-of-the-Science Conference on Manifestations and Management of Chronic Insomnia in Adults defined chronic insomnia as 30 days or more of the previously described symptoms. People with chronic insomnia frequently complain of fatigue; mood changes, such as irritability and depression; difficulty concentrating; and impaired performance.

Chronic insomnia often is related to medical or psychiatric disorders. Factors such as pain, immobility, and hormonal changes associated with pregnancy or menopause also can cause insomnia. Interrupted sleep can accompany other sleep disorders such as RLS and sleep apnea. Many health problems worsen during the night. Heart failure, respiratory disease, and gastroesophageal reflux can cause frequent awakenings during the night. Mood and anxiety disorders are the most frequent cause of insomnia in people with psychiatric diagnoses.

A number of drugs can lead to poor-quality sleep. Drugs commonly related to insomnia are caffeine, nicotine, stimulating antidepressants, alcohol, and recreational drugs. Although alcohol initially may induce sleep, it often causes disrupted and fragmented sleep. Sleep also is disrupted in people undergoing alcohol or sleep medication withdrawal.

**Diagnosis**

The diagnosis of insomnia is aided by a sleep history. Questions should address both sleep and daytime functioning. If the person has a bed partner, it is important to ask the partner if the person with insomnia snores, has unusual movement during sleep, or is excessively drowsy during the day. Because sleep needs vary from person to person, a 1- to 2-week sleep diary can be useful in diagnosing the sleep problem and in serving as a baseline for treatment effects. Other factors that need to be explored are the use of drugs such as caffeine, tobacco, and alcohol, as well as prescription and over-the-counter drugs that affect the sleep-wake cycle. Identification of physical and psychological factors that interfere with sleep also is important. Actigraphy or PSG may be used as diagnostic tools. PSG is the most sensitive tool to evaluate sleep and wakefulness. However, it is expensive and, because of the numerous monitoring electrodes, can actually disrupt sleep. Its use as a diagnostic tool for insomnia is usually limited to causes in which other sleep disorders, such as sleep apnea, are suspected.

**Treatment**

Treatment of insomnia includes education and counseling regarding better sleep habits (sleep hygiene), behavioral therapy aimed at changing maladaptive sleep habits, and the judicious use of pharmacologic interventions. The cause and duration of insomnia are particularly important in deciding on a treatment strategy. With acute insomnia, treatment stresses the development of good sleep hygiene and judicious short-term use of sedatives or hypnotics. Long-term and chronic insomnia require careful assessment to determine the cause of the disorder. Depending on the findings, treatment options include behavioral strategies such as relaxation therapy, sleep restriction therapy, stimulus control therapy, and cognitive therapy. Sedatives and hypnotics, which tend to become less effective with time and may cause dependence, are used with caution.

Sleep hygiene refers to a set of rules and information about personal and environmental activities that affect sleep. These rules include establishing a regular wake-up time to help set the circadian clock and regularity of sleep onset, maintaining a practice of sleeping only as long as needed to feel refreshed, providing a quiet sleep environment that is neither too hot nor too cold, and avoiding the use of alcohol and caffeine (coffee, cola, tea, chocolate) before retiring for sleep.

Behavioral therapies include relaxation therapy, sleep restriction therapy, stimulus control therapy, and cognitive therapy. Relaxation therapy is based on the premise that people with insomnia tend to display high levels of physiologic, cognitive, and emotional arousal during both the day and the night. Sleep restriction therapy consists of curtailing the amount of time spent in bed in an effort to increase the sleep efficiency (time asleep/time in bed). People with insomnia often increase their time in bed in the misguided belief that it will provide more opportunity to sleep. Stimulus control therapy focuses on reassociating the bed and bedroom with sleep rather than sleeplessness. It is important that the bed and bedroom be identified with sleep and not with reading, watching television, or working. People who cannot fall asleep should be instructed to turn on the light and do something else outside the bed, preferably in another room. Cognitive therapy involves the identification of dysfunctional beliefs and attitudes about sleep and replacing them with more adaptive substitutes.
Pharmacologic treatment usually is reserved for short-term management of insomnia—either as the sole treatment or as adjunctive therapy until the underlying problem can be addressed. The most common type of agents used to promote sleep are the benzodiazepines (BZDs) and the newer benzodiazepine receptor agonists (BZRAs). The BZRAs (zolpidem [Ambien], zaleplon [Sonata], and eszopiclone [Lunesta]) are often preferred because of their rapid onset and shorter duration of action. Ramelteon (Rozerem) is the first and only nonscheduled drug approved by the U.S. Food and Drug Administration for treatment of insomnia. It was approved in 2005 for sleep-onset insomnia and can be prescribed for long-term use. Ramelteon is a melatonin receptor agonist with high selectivity for melatonin (MT)-1 and MT-2 receptors in the SCN of the hypothalamus, receptors that are believed to be involved in sleep promotion and maintenance of the circadian rhythm. Ramelteon has no appreciable binding to gamma-aminobutyric acid (GABA) receptors and hence no anxiolytic or abuse potential.

Sedating antidepressants also may be prescribed, particularly when insomnia is due to depression. Antihistamines have sedative effects and may be used to induce sleep. The most commonly used agents are diphenhydramine and doxylamine. Most over-the-counter sleep medications include an antihistamine. Advective effects of antihistamines include daytime sleepiness, cognitive impairments, and anticholinergic effects. Falls and fractures are more frequent in people using antihistamines. Adverse effects of antihistamines include daytime sleepiness, cognitive impairments, and anticholinergic effects. Falls and fractures are more frequent in people using hypnotic or other psychotherapeutic agents. Melatonin, available in both natural and synthetic forms, is one of the most popular over-the-counter sleep aids.

**SLEEP DISORDERS**

- Primary sleep disorders include insomnias (repeated difficulty with sleep initiation, duration, and quality of sleep), narcolepsy (characterized by excessive daytime sleepiness), breathing-related sleep disorder (disordered respirations during sleep), and circadian rhythm sleep disorder (misalignment between sleep pattern and societal norms).
- The parasomnias, which are undesirable physical phenomena that occur almost exclusively during sleep or are exaggerated by sleep, include nightmares, sleepwalking, and sleep terrors.

**Narcolepsy**

Narcolepsy is a syndrome characterized by abnormal sleep tendencies, including excessive daytime sleepiness, disturbed nocturnal sleep, and manifestations related to REM sleep such as cataplexy (brief periods of muscle weakness), hypnagogic hallucinations, and sleep paralysis. Daytime sleepiness is the most common initial symptom of narcolepsy. It is most apparent in boring, sedentary situations and often is relieved by movement. Although the sleepiness that occurs with narcolepsy is similar to that experienced after sleep deprivation, it is different in that no amount of nighttime sleep produces full alertness. The periods of daytime sleep usually are brief, lasting 30 minutes or less, and often are accompanied by brief interruptions of speech or irrelevant words, lapses in memory, and nonsensical activities. Cataplexy is characterized by brief periods of muscle weakness brought about by emotional reactions such as laughter, anger, or fear. Sleep paralysis is a terrifying experience that occurs on falling asleep or on awakening, during which people find themselves unable to move, speak, or even breathe deeply.

Hypnagogic hallucinations are vivid hallucinations that occur at the onset of sleep. Similar hallucinations may occur on awakening (i.e., hypnopompic hallucinations). These hallucinations are usually visual or auditory, although tactile components may occur. The exact boundary between hypnagogic/hypnopompic hallucinations and dreams is not a clear one.

Generally beginning in puberty, the peak incidence of narcolepsy is between ages 15 and 30. The mechanisms underlying the manifestations of narcolepsy appear to be linked to an abnormality in REM sleep regulation. The occurrence of REM sleep at sleep onset or within 10 to 15 minutes of sleep onset is the most characteristic and striking manifestation of the disorder. Periods of sleep-onset REM are thought to indicate impaired sleep–wake regulation rather than increased need for REM sleep. The sleep paralysis, dreamlike hallucinations, and the loss of muscle tone that occur during cataplexy are similar to behaviors that occur during REM sleep.

**Etiology**

Although the cause of narcolepsy is unknown, there are indications that the disorder may have a genetic component. People with narcolepsy have been shown to have an unusually high rate of a specific human leukocyte antigen (HLA) subtype (HLA DQB1-0602). This association is seen in approximately 85% of cases with cataplexy. Importantly, this association is substantially lower in people who have received the diagnosis of narcolepsy, but do not have cataplexy. The strong association between HLA type and cataplexy raises the possibility that narcolepsy is an autoimmune disease.

Recent research has suggested a link between a newly identified group of neurotransmitters called hypocretins and narcolepsy. The hypocretins (hypocretin 1 and hypocretin 2) are secreted by cells in the area of the hypothalamus that is related to wakefulness. The results of several studies suggest that narcolepsy with cataplexy is caused by loss of hypocretin -producing neurons. Narcolepsy may also be caused by neurological insults that affect levels of hypocretin, such as hypthalamic lesions, and vascular, or inflammatory, brain trauma.
Diagnosis and Treatment

Sleep laboratory studies are usually required for accurate diagnosis of narcolepsy. Both daytime and nighttime studies are done. Nighttime PSG is usually performed to determine the presence and severity of sleep apnea, limb movement disorders, and nocturnal sleep disturbance. A daytime MSLT usually is done the next day. People with narcolepsy are observed to have a short period of sleep latency (<8 minutes, often <5 minutes) during daytime studies, along with a rapid onset of REM sleep (usually within 10 minutes). A mean sleep latency of less than 8 minutes and two or more periods of sleep-onset REM during the repeated nap opportunities are considered diagnostic of narcolepsy.36

There is no known cure for narcolepsy. Therefore, the goal of treatment is symptom management.36 Patient education about good sleep hygiene, maintaining regular sleep patterns, and avoiding sleep deprivation should be included in the treatment plan for narcolepsy. People should also be warned about the risks of driving when excessively sleepy. Several short (15- to 20-minute) naps per day may decrease excessive daytime sleepiness. Unfortunately, such lifestyle changes are usually insufficient to adequately control the symptoms of narcolepsy.

Pharmacological treatment of narcolepsy focuses on the use of stimulant medications such as methylphenidate (Ritalin), amphetamines (e.g., Adderall, Desoxyn), modafinil (Provigil), and armodafinil (Nuvigil), which are FDA-approved for the treatment of narcolepsy. Sodium oxybate (Xyrem), a CNS depressant, is FDA-approved for the treatment of cataplexy and excessive daytime sleepiness. It is believed to help by consolidating and improving the quality of nighttime sleep. Tricyclic antidepressants and the selective serotonin reuptake inhibitors (SSRIs) have been used successfully to treat the cataleptic attacks.36

Sleep-Related Movement Disorders

A variety of spontaneous limb movements occur during normal sleep. Many of these movements demonstrate characteristic rates and patterns during certain stages of sleep. Many movement disorders occur during stage 2 NREM sleep. Some occur during normal sleep in all people at some time or another. Others are not part of normal sleep patterns and can be disruptive of sleep. Among the abnormal motor disorders are periodic limb movement disorder (PLMD) and RLS.30,31

Periodic Limb Movement Disorder

PLMD is characterized by episodes of repetitive movement of the large toe with flexion of the ankle, knee, and hip during sleep.30,31 It can occur simultaneously in both legs, alternate between legs, or occur unilaterally. The disorder results in disrupted sleep quality and daytime functioning. The condition occurs most frequently during light (stages 1 and 2 NREM) sleep compared with deep (stages 3 and 4 NREM) sleep and REM sleep. The incidence of the disorder, which occurs equally in men and women, increases with age. The disorder frequently accompanies RLS.30,32 People with PLMD are often unaware of periodic limb movements, but their bed partners may report the symptoms.

The cause of PLMD is largely unknown. It has been observed that the movements mimic the Babinski reflex, suggesting removal of an excitatory influence over a subcortical inhibitory system allowing for facilitation of abnormal movements during sleep. There is also an autonomic response that accompanies the periodic leg movements. A rapid rise in heart rate and arterial BP followed by a bradycardia and return of BP to normal.31 The disorder is considered a diagnosis of exclusion, and diagnosis is facilitated with use of EMG recordings from both tibialis anterior muscles. A person must experience both the periodic leg movements in sleep (PLMS) and a disruption in daytime functioning to receive the diagnosis of PLMD.30

Restless Legs Syndrome

RLS is a sleep disorder characterized by
1. An urge to move the limbs with or without sensations
2. Worsening at rest or inactivity
3. Improving with activity or movement
4. Worsening in the evening or night29,30,31

The prevalence of the condition peaks in middle age and reportedly occurs in 2% to 20% of the older adult population. Although the prevalence increases with age, it has a variable age of onset and can even occur in children. Approximately 7 out of 10 people may experience the disorder sometime in their lifetime.30

The disorder, which is thought to have its origin in the CNS, can occur as a primary or secondary disorder. There is a high familial incidence of primary RLS, suggesting a genetic disorder. Secondary causes of RLS include iron deficiency, neurologic disorders such as spinal cord and peripheral nerve lesions, pregnancy, uremia, and medications. Although the neurologic basis of RLS has not been determined, recent research suggests that it may involve homeostatic mechanisms that regulate the influx and efflux of iron from cells of the CNS that regulate motor movements.33 Cerebrospinal fluid ferritin (the main iron storage molecules in the CNS) levels are lower in people with RLS. Of interest is the role of iron in dopaminergic transmission in the CNS. Iron is an important cofactor for tyrosine hydroxylase, the rate-limiting enzyme in dopamine synthesis, and also plays a major role in the functioning of postsynaptic dopamine receptors.33

Diagnosis of RLS is based on a history of
1. A compelling urge to move the legs, usually associated with unpleasant sensations
2. Motor restlessness, as seen by activities such as pacing, tossing and turning in bed, or rubbing the legs
3. Symptoms that become worse at rest and are relieved by activity
4. Symptoms that are worse in the evening or at night33,34

Laboratory tests to determine secondary causes of RLS usually are done. Because RLS may be a symptom of iron deficiency,
serum ferritin and iron saturation should be assessed. This is important because iron deficiency is frequently present in the absence of anemia. Sleep studies are usually not required because the condition can be diagnosed on the basis of history and clinical findings.

Treatment of RLS varies depending on the severity of symptoms. Dopaminergic agents are the first-line drugs for most people with RLS. These include ropinirole (Requip), pramipexole (Mirapex), levodopa, and carbidopa (Sinemet). Antiseizure agents (gabapentin), BZDs (e.g., clonazepam, temazepam), and opioids (e.g., codeine, propoxyphene, or oxycodone) are second-line agents. Although pharmacologic treatment is helpful for many people with RLS, those with mild symptoms may not require medications. For many people, deliberate manipulation of the muscles through ambulation, kicking movements, stretching, or massage may provide relief. Good sleep habits are important. Because a high prevalence of iron deficiency has been found among people with RLS, treatment of the deficiency may improve or resolve symptoms.

Sleep-Related Breathing Disorders

Sleep-disordered breathing (SDB) is associated with several conditions that result in altered respirations. Each condition has specific clinical presentations along with methods of diagnosis, treatment, and follow-up. These breathing disorders result in sleep deprivation and interfere with work, driving, and social activities. The most common SDB is sleep apnea.

**Sleep Apnea**

Sleep apnea is an SDB, accompanied by daytime symptoms, most often excessive sleepiness. There are two types of sleep apnea: central and obstructive. Central sleep apnea is not common, and the etiology is unknown. However, it is associated with underlying pathological conditions such as Cheyne-Stokes breathing or environmental causes such as high-altitude periodic breathing. It is characterized by a cessation or decrease in ventilatory effort during sleep and is usually associated with oxygen desaturation. Obstructive sleep apnea (OSA) syndrome, which is caused by upper airway obstruction and characterized by snoring, disrupted sleep, and excessive daytime sleepiness, is the much more common type. Although airflow ceases, respiratory muscles continue to function. This is one of the features that distinguishes central sleep apnea from OSA. The majority of people with central sleep apnea also have some obstructive events.

**Obstructive Sleep Apnea/Obstructive Sleep Apnea–Hypopnea Syndrome**

Apnea is defined as cessation of airflow through the nose and mouth for 10 seconds or longer. The apneic periods typically last for 15 to 120 seconds, and some people may have as many as 300 to 500 apneic periods per night. An accompanying reduction in tidal volume due to a decrease in the depth and rate of respiration (called hypopnea) is associated with a decrease in arterial oxygen saturation. OSA is the most appropriate term applied to this syndrome. However, an older terminology, sleep apnea–hypopnea syndrome (OSAH or OSAHS), is still frequently used. The average number of apnea–hypopnea periods per hour is called the apnea–hypopnea index (AHI). An adult may experience up to five events an hour without symptoms. As the AHI increases, so does the severity of symptoms. An AHI of five or greater in combination with reports of excessive daytime sleepiness is indicative of OSA.

**Pathogenesis.** A critical pathophysiologic feature of OSA is sleep-related partial or full collapse of the upper airway at the level of the pharynx. All skeletal muscles except the diaphragm undergo a decrease in tone during sleep. This loss of muscle tone is most pronounced during REM sleep. The loss of muscle tone in the upper airways predisposes to airway obstruction as the negative airway pressure produced by contraction of the diaphragm brings the vocal cords together, collapses the pharyngeal wall, and sucks the tongue back into the throat (Fig. 21.6). Airway collapse is accentuated in people with conditions that cause narrowing of the upper airway or weakness of the throat muscles.

![FIGURE 21.6 • Principal mechanism of OSA. When the person is awake (top), the airway is kept open by the activity of the pharyngeal musculature. During sleep (bottom), this activity is decreased, causing airway obstruction, most commonly in the area behind the uvula, soft palate, and posterior tongue.](image)
**Etiology.** Conditions that predispose to OSA include male gender, increasing age, a positive family history, and obesity. Alcohol and other drugs that depress the CNS tend to increase the severity of obstructive episodes. Most people who develop sleep apnea are obese. Large neck girth in both male and female snorers is highly predictive of sleep apnea. Neck circumferences greater than 40 cm are correlated with OSA, even more so than body mass index (BMI).40 Men have a higher risk for OSA than women. The reason for this is not entirely clear, but gonadal hormones may play a role.40 Postmenopausal women are at higher risk than premenopausal women. People with specific endocrine disorders, namely, acromegaly, Cushing syndrome, hypothyroidism, and diabetes mellitus, are at higher risk for OSA. In each of these disorders, hormonal imbalances lead to structural distortion of the airways that leads to obstruction.

**Clinical Manifestations.** OSA is characterized by loud snoring and labored breathing interrupted by periods of silence soon followed by apnea.1-40 Abnormal gross motor movements during sleep are common. In many cases, the snoring precedes by many years the onset of other signs of sleep apnea. The most common presenting symptoms are persistent and excessive daytime sleepiness and a history of snoring.32 Other symptoms include morning headache, memory and judgment problems, irritability, difficulty concentrating, and depression. People with OSA are more likely to fall asleep at inappropriate times and have higher rates of automobile and work-related accidents. Men may complain of impotence. In children, a decline in school performance may be the only indication of the problem.

Increased sympathetic activity can lead to an increased risk of cardiovascular disease.1 OSA is associated with sleep-related cardiac arrhythmias, hypertension, and heart failure. Frequent apneic periods may result in increased systemic and pulmonary BP s and significant decreases in PO2 and increased PCO2.1 The morning BP has been shown to increase almost linearly with increasing apnea episodes. In severe cases, pulmonary hypertension, polycythemia, and cor pulmonale may develop. The signs and symptoms of OSA are summarized in Chart 21.2.

**Diagnosis.** OSA usually is suspected from a history of snoring, disturbed sleep, and daytime sleepiness. Nocturia also is a common finding and is commonly misinterpreted in men as benign prostatic hypertrophy.32 A definitive diagnosis is accomplished with sleep studies done in a sleep laboratory using PSG.37,38 In the past, this procedure required an overnight stay in a sleep laboratory. The procedure consists of EEG and EOG to determine the sleep stages; monitoring of the airflow; an ECG to detect arrhythmias; methods to measure ventilatory effort; and pulse oximetry to detect changes in oxygen saturation. An MSLT may be done to rule out narcolepsy in people who exhibit excessive daytime sleepiness. Home evaluation using PSG may be used to screen for sleep apnea.32 The Center for Medicare and Medicaid Services (CMS) announced that it would pay for continuous positive airway pressure (CPAP) treatment on the basis of portable testing. Reimbursement is tied directly to demonstration of benefits of treatment.33 This determination was made because laboratory testing for OSA did not provide obvious benefits in outcomes compared to home testing.43

**Treatment.** The treatment of OSA is determined by the severity of the condition. Behavioral measures may be the only treatment needed for people with mild OSA. These include weight loss, eliminating evening alcohol and sedatives, and proper bed positioning. Weight loss often is beneficial for people with OSA. In many instances, the SDB events are confined to the supine sleeping position, so that training the person to sleep in the lateral position may help to alleviate the problem.

Oral or dental appliances that displace the tongue forward and move the mandible to a more anterior and forward position may be an option for persons with mild to moderate OSA. People who snore but do not have sleep apnea also may use these devices. They should be fitted by a dentist or orthodontist experienced in their use. Side effects of the devices include excessive salivation and temporomandibular joint discomfort.

The principle treatment for OSA remains positive pressure delivered by nasal or naso-oral continuous positive airway pressure (NCPAP) at night. This method uses an occlusive nasal mask or a device that fits into the nares, an inspiratory valve and tubing, and a blower system to generate positive pressure. The main difficulty with NCPAP is that many people find it unacceptable. Common complaints include dryness of the mouth, claustrophobia, and noise.

Several surgical procedures have been used to correct airway obstruction, including nasal septoplasty (i.e., repair of the nasal septum) and uvulopalatopharyngoplasty (i.e., excision of excess soft tissue on the palate, uvula, and posterior pharyngeal wall). Both of these procedures have met with limited success. Severe cases of sleep apnea may require a tracheostomy (i.e., surgical placement of a tube into the trachea for the purpose of maintaining an open airway). The tracheostomy tube remains occluded during the day and is opened during the night.

### Chart 21.2

**SIGNS AND SYMPTOMS OF OBSTRUCTIVE SLEEP APNEA**

- Excessive daytime sleepiness
- Noisy snoring
- Observed apnea
- Insomnia
- Abnormal movements during sleep
- Morning headaches
- Cognitive and personality changes
- Sexual impotence
- Systemic hypertension
- Pulmonary hypertension, cor pulmonale
- Polycythemia
The Pickwickian Syndrome. The pickwickian syndrome, named after the fat boy in Charles Dickens’ *The Posthumous Papers of the Pickwick Club*, published in 1837, is characterized by obesity, hypersonolence, periodic breathing, hypoxemia, and right-sided heart failure. This condition is now called obesity hypoventilation syndrome (OHS). OHS is defined as

1. A BMI ≥ 30 kg/m²
2. Chronic hypoventilation leading to hypoxia and hypercapnia when awake
3. Sleep-disordered breathing

Approximately 90% of people with OHS have an obstructive breathing disorder consistent with OSA.

Parasomnias
Parasomnias are undesirable episodes or behaviors that occur during sleep. They include nightmares, sleepwalking (somnambulism), and sleep terrors. Sleepwalking, sleep terrors, and bed-wetting often are seen in children and may be considered normal to some degree at a certain age. They are less common in adults and may be indicative of other pathologic processes. For example, sleepwalking and sleep terrors may occur in people with poorly controlled cardiac insufficiency after myocardial infarction. In rare cases, sleepwalking and sleep terrors may be the first sign of a slowly evolving brain tumor. Finally, sleepwalking and sleep terrors may be triggered by disorders interacting with the sleep–wake cycle. Particularly in older adults, health problems such as a febrile illness may enhance NREM sleep nightmares, sleep terrors, and sleepwalking.

Nightmares
Nightmares are vivid and terrifying nocturnal episodes in which the dreamer is abruptly awakened from sleep. Usually there is difficulty returning to sleep. Nightmares significantly affect 10% to 50% of children between 3 and 5 years of age to the degree that parents are disturbed. About half of adults admit to an occasional nightmare; 1% of adults report having a nightmare at least once a week. Most nightmares occur during REM sleep. Most REM-altering disorders and medications that affect REM sleep affect dreaming.

Nightmares are a defining symptom of posttraumatic stress disorder (PTSD). These nightmares occur after intensely frightening or highly emotional experiences and are associated with disturbed sleep and daytime hyperarousability. People with PTSD report awakening from dreams that involve reliving the trauma. The frequency of PTSD nightmares increases with the severity of trauma, and they can persist for long periods after the traumatic experience. It has been reported that 30% of veterans of the Vietnam War are affected by PTSD.

Sleepwalking and Sleep Terrors
Sleepwalking and sleep terrors usually occur during stages 3 and 4 of NREM sleep. Because stages 3 and 4 are more prolonged during the first third of the night, sleepwalking and sleep terrors usually occur during this time. Sleep terrors are characterized by sudden, loud, terrified screaming and prominent autonomic nervous system activation (tachycardia, tachypnea, diaphoresis, and mydriasis). Sleepwalking is characterized by complex automatic behaviors, such as aimless wandering, furniture rearranging, urinating in closets, and going outdoors. During a typical episode, the sleepwalker appears dazed and relatively unresponsive to the communication efforts of others. On awakening, there may be a brief period of confusion or disorientation. The sleepwalker usually has no memory or only a vague awareness of what has happened.

Sleep terrors are more common in children and are discussed later in the chapter. In children, sleepwalking usually is a benign and self-limiting disorder. Prevalence of sleepwalking in adults was estimated at 1.7% of the general population in one study; 0.6% of the study sample reported sleepwalking occurring at least once a week. Sleep deprivation may precipitate sleepwalking episodes in adults. An association between sleepwalking and psychiatric disorders, and use of psychotropic medications has been found in some studies.

Diagnosis and treatment of sleepwalking and sleep terrors depends on age. Because most children eventually outgrow the disorders, parents may simply need to be reassured and instructed in safety measures. Insufficient sleep may precipitate episodes of sleepwalking. Therefore, parents should make certain that the child goes to bed on time and gets enough sleep. In adults, a through medical, psychiatric, and sleep history should be done to eliminate other causes of the disorder, such as Parkinson disease, hyperthyroidism, and migraine. Because sleepwalking can be dangerous, it is important that the environment be safe. Dangerous objects should be removed and bolts should be placed on doors and windows. No attempt should be made to interrupt the sleepwalking event because such efforts may be frightening.

Pharmacologic treatment of sleepwalking includes the selective use of the BZDs (particularly diazepam and clonazepam) or the tricyclic antidepressant imipramine. In older adults, treatment focuses on reversing the underlying causes of delirium. Because medications are a frequent cause of delirium in older adults, a complete drug history should be done with the intent of eliminating medications that might be causing the disorder.

**IN SUMMARY**

Sleep disorders include the circadian rhythm sleep disorders, insomnia, narcolepsy, sleep-related movement disorders, sleep apnea, and the parasomnias. Sleep problems due to *alterations in circadian rhythm* are related to intrinsic factors (free-running disorder, ISWR, advanced sleep phase disorder, and delayed sleep phase disorder) and acute shifts in the sleep–wake cycle (jet lag and shift work). *Insomnia* represents a subjective problem of insufficient or nonrestorative sleep despite an adequate opportunity to sleep. It includes...
acute and chronic problems in falling asleep and maintaining sleep, waking up too early, or nonrefreshing sleep.

Narcolepsy is a disorder of daytime sleep attacks, cataplexy, hallucinations occurring at the onset of sleep, and sleep paralysis. Among the movement disorders that occur during sleep are PLMD and RLS. PLMD is characterized by episodes of repetitive movement of the large toe with flexion of the ankle, knee, and hip during sleep, usually involving both legs. RLS is a neurologic disorder characterized by an irresistible urge to move the legs, usually owing to a “creeping,” “crawling,” or uncomfortable sensation. It usually is worse during periods of inactivity and often interferes with sleep.

Obstructive sleep apnea (OSA) is a serious, potentially life-threatening disorder characterized by brief periods of apnea or breathing cessation during sleep, loud snoring interrupted by periods of silence, and abnormal gross motor movements. It is accompanied by complaints of persistent daytime sleepiness, morning headache, memory and judgment problems, irritability, difficulty concentrating, and depression. OSA also is associated with sleep-related cardiac arrhythmias, hypertension, and heart failure. The parasomnias are undesirable physical phenomena that occur almost exclusively during sleep or are exaggerated by sleep. They include nightmares, sleepwalking, and sleep terrors.

Sleep Disorders in Children

Although sleep complaints are common among adults, children usually do not complain about sleep problems, although their parents might. The usual concerns of parents include irregular sleep habits, insufficient or too much sleep, nightmares, sleep terrors, sleepwalking, and bed-wetting. Complaints of excessive daytime sleepiness or sleep attacks not accounted for by an inadequate amount of sleep may be due to a more serious health or sleep problem (e.g., narcolepsy). In these cases, a careful sleep history, physical examination, and other diagnostic tests may be needed. Three of the more common sleep problems of children are discussed in this section of the chapter, including sleep terrors, confusional arousals, and sleepwalking.

Sleep Terrors. Sleep terrors are marked by repeated episodes of awakening from sleep. They usually occur during the first third of the night lasting between 30 seconds and 3 minutes. The peak onset is usually is between 5 and 7 years of age. The course is variable, usually occurring at intervals of days or weeks. The disorder gradually resolves in children and usually disappears during adolescence. In a typical episode, the child sits up abruptly in bed, appears frightened, and demonstrates signs of extreme anxiety, including dilated pupils, excessive perspiration, rapid breathing, and tachycardia. Until the agitation and confusion subside, efforts to comfort or help the child are futile. There usually is no memory of the episode. Occasionally, the child recounts a sense of terror on being aroused during a night terror, but there is only fragmentary recall of dreamlike images. Treatment consists primarily of educating and reassuring the family. The child should be assisted in settling down without awakening. The child must be protected if he or she gets up and walks about during the episodes.
Confusional Arousals. Confusional arousals are common in infants and toddlers. They usually occur during the first third of the night when the brain is partially asleep while remaining partially awake. During these events, children present with marked confusion, slow and inappropriate responses to questions, and nonpurposeful activities. They do not express fear, terror, or panic. Children spontaneously return to sleep and have no recollection of the event in the morning. Recovery from sleep deprivation tends to increase the incidence of confusional arousals.

Sleepwalking. Sleepwalking, common in children between the ages of 5 and 12 years, involves repeated episodes of complex motor movements that lead to leaving the bed and walking without the child being conscious of the episode or remembering that it occurred. As with sleep terrors, it normally occurs in NREM sleep stages 3 and 4 during the first third of the sleep period. A sleepwalking episode typically lasts for a few minutes to half an hour, during which time the child sits up; makes purposeful movements such as picking at the bed coverings; then proceeds to semipurposeful movements such as getting out of bed, walking around, opening doors, dressing, or going to the bathroom. Often they end up in the parent’s bedroom. Commonly, they are unresponsive to the efforts of others to communicate with them. Confusion and disorientation are typical of the events, and on awakening there is no memory of the event. There may be manifestations of extreme autonomic nervous system activity such as tachycardia, rapid breathing, perspiration, and urination.

Sleepwalking is reported in approximately 15% of children. Frequent sleepwalking events, defined as one to four times a week, occur in 1% to 6% of children. It occurs more commonly in boys than in girls and is more frequent in children in whom there is a family history of sleepwalking. The onset usually is between 4 and 8 years of age, and it lasts several years. Usually symptoms resolve by the end of the teens or in the early twenties. The primary concern is injury during an episode. Children may bump into things, fall down stairs, or even leave their home during an episode. Therefore, gates should be placed across stairs and windows and doors should be locked so the child cannot leave the house.

Sleepwalking is reported in approximately 15% of children. Frequent sleepwalking events, defined as one to four times a week, occur in 1% to 6% of children. It occurs more commonly in boys than in girls and is more frequent in children in whom there is a family history of sleepwalking. Therefore, gates should be placed across stairs and windows and doors should be locked so the child cannot leave the house.

Sleep and Sleep Disorders in Older Adults

Complaints of difficulty sleeping occur in over 50% of adults 65 years of age and older, and 30% of older adults experience chronic insomnia. However, this increased prevalence should not be expected as a phenomenon of aging. Instead, the difficulties with sleeping are often the result of medical and psychosocial comorbidities. The consequences of chronic sleep problems in older adults can be considerable. Left uncorrected, a sleep disorder affects the quality of life. Loss of sleep and use of sedating medications may lead to falls and accidents. Sleep-related disorders of breathing may have serious cardiovascular, pulmonary, and CNS effects.

There are a number of changes that occur in the sleep–wake cycle as a person ages. Older adults have repeated and frequent interruptions of sleep with longer periods of wakefulness along with a shorter duration of stages 3 and 4 sleep. Although REM sleep tends to be preserved, the deepest stages of NREM sleep frequently are reduced. Compared with younger people, adults in their 70s need 30 to 60 minutes less sleep than adults in their 20s. They often take longer to fall asleep, they awaken earlier, and they have more nighttime arousals. Environmental influences, particularly auditory stimuli, often are more disruptive in older adults. With an increase in nighttime wakefulness, there is an increase in daytime fatigue and daytime napping. An often-overlooked cause of nocturnal awakenings in the older adult population is nocturia or need to urinate during the night.

The causes of sleep disorders in older adults include age-related changes in sleep architecture, secondary sleep disturbances, primary sleep disorders, lack of exercise, and poor sleep habits. Factors that predispose to secondary sleep disturbances include physical and mental illness, medication effects, and emotional stress. A variety of medical illnesses contribute to sleep disorders in older adults, including arthritic pain, respiratory problems, cardiac disease, and neurologic disorders. Nightmares and nighttime fears are common in older adults with Parkinson disease, particularly those who are receiving levodopa. Psychiatric illness, such as depression, is a common cause of disturbed sleep in this age group. Primary sleep disorders such as sleep apnea, RLS, and PLMD also increase in old age. Many medications used to treat chronic medical and psychiatric conditions have stimulating effects and interfere with sleep. These include some of the antidepressants, decongestants, bronchodilators, corticosteroids, and antihypertensives. Certain over-the-counter medications can cause or exacerbate sleep disturbances. Alcohol use also may serve as a deterrent to sleep in older adults. Sleep–wake problems may be compounded further by inappropriate interventions initiated by the older adult, his or her family, or health care providers.

Sleep also is disturbed in disorders characterized by dementia. Episodes of nocturnal wandering, confusion, and delirium can occur despite normal daytime functioning. People with Alzheimer disease often have increased periods of nighttime awakening and daytime napping.

Diagnosis of sleep disorders in older adults requires a comprehensive sleep history, inquiries about pain and anxiety or depression, review of current sleep hygiene practices, drug use history, spousal or bed partner reports, a comprehensive physical examination, and appropriate laboratory tests. Interventions to assist the older adult include good sleep habits. The development of a sleep ritual is essential. Treatment of a medical disorder and changes in medication regimes and timing of medication doses can often improve sleep. Avoidance of alcohol and stimulants before bedtime and improving sleep hygiene are other measures that can be used to improve sleep. Although hypnotics can be used to treat transient insomnia, they often fail to provide long-term relief of chronic sleep disturbances.
IN SUMMARY

Circadian rhythms and sleep patterns are established early in life. In the newborn, REM sleep occurs at sleep onset, and periods of sleep and awakening are distributed throughout the day. As the cyclic structure of the sleep–wake cycle progresses, the amount of time spent in REM sleep decreases. By the time the child is 6 months of age, three distinct stages of NREM sleep occur. At 9 months, about 70% to 80% of infants sleep through the night and may nap at predictable times during the day. Although sleep complaints are common among adults, children usually do not complain about sleep problems, although their parents might. The usual concerns of parents include irregular sleep habits, insufficient or too much sleep, nightmares, sleep terrors, and sleepwalking.

Complaints of sleep disorders are common in older adults. The sleep–wake cycle changes that occur with aging are evidenced by more fragmented sleep and shorter duration of stage 3 and 4 sleep. Older adults also have more health problems that interrupt sleep, they are apt to be on medications that interfere with sleep, and they are more likely to have sleep disorders such as insomnia, RLS, and sleep-disturbed breathing. Left uncorrected, sleep disorders in older adults affect the quality of life. Loss of sleep and use of sedating medications may lead to falls and accidents.

Chapter 21 Sleep and Sleep Disorders

Visit thePoint http://thePoint.lww.com for animations, journal articles, and more!
The purpose of this chapter is to present the pathophysiology of psychiatric disorders and the disorders of dementia. A neurophysiological framework for psychiatric disorders is discussed, and alterations in brain functioning are related to specific manifestations of symptoms. Common psychiatric disorders and their treatments are described. The pathophysiology of psychiatric and dementia disorders is a vast, complicated area of neuroscience. The reader is advised to review Chapter 17, Organization and Control of Neural Function, and Chapter 9, Stress and Adaptation, prior to reading this chapter. In addition, it is important to keep in mind that there is overwhelming evidence that mental illness should be viewed on a spectrum with “normal experience” and that strongly evidenced causal factors for many disorders of emotion, thought, and memory include psychosocial, developmental, environmental, and biological factors.
lives with serious mental illness, such as schizophrenia, bipolar disorder, or major depression. Unfortunately, children are not exempt. One in 10 children reports significant functional impairment in their day-to-day lives at home and school resulting from serious mental health problems and psychiatric disorders. The National Comorbidity Survey Replication (NCS-R) of 10,000 English-speaking respondents found that over half of mental illness begins before the age of 14 and three quarters by age 24. The most common mental health problems in the United States are depression, anxiety, and substance abuse. However, it is important to note that comorbidities are the rule rather than the exception. Therefore, most often, a person has several psychiatric diagnoses concurrently, not just one. In several large national surveys, more than one disorder was present in a person 60% of the time.

### The Diagnosis of Psychiatric Disorders

Psychiatric diagnoses are made through the use of the *Diagnostic and Statistical Manual of Mental Disorders (DSM)*. These disorders consist of symptom categories or syndromes of observable traits that often occur together. The first DSM was published in 1951 with subsequent revisions, DSM-II (1968), DSM-III (1980), DSM-III-R (1987), DSM-IV (1994), DSM-IV-TR (2000), and the new DSM-V, which will be released in 2013. A different international coding system developed by the World Health Organization, the *International Statistical Classification of Diseases and Related Health Problems (ICD-10)*, corresponds with some of the DSM codes.

Psychiatric diagnosis in the DSM is based on observable symptom clusters that are researched and agreed upon by a panel of mental health experts, until most recently, exclusively psychiatrists. The DSM is atheoretical, that is, there is no assumption as to causation, underlying theoretical speculations about the etiology, or the subjective experience of the person. At present, there is only one diagnosis in the DSM that does include a causative factor. The DSM states that post-traumatic stress disorder (PTSD) is caused by exposure to a traumatic event. There are no biomarkers for any psychiatric diagnosis. Instead, psychopathology is determined by symptoms that rely on subjective judgments, which are largely based on social norms.

When a clinician makes a diagnosis, it does not mean that everyone with that diagnosis will have the same underlying physiological changes. What is considered pathological is culture bound and changes according to societal values, mores, and behaviors that are considered acceptable at the time. For example, in the late 1800s, hysteria in women was rampant. Today, hysteria is rarely seen and is not a DSM diagnosis. Prior to the DSM-IV, homosexuality was considered a psychiatric disorder. In some Southeast Asian cultures, amok or koro may be diagnosed in men. Amok is an episode of murderous rage followed by amnesia, while koro is characterized by the certainty of the man that his genitals are retracting into his body. Amok and koro are considered culture-bound syndromes and are included in an appendix of the revised edition of the DSM-IV.

### Understanding Psychiatric Disorders

Luhrmann, a cultural anthropologist, explains that there are essentially two frameworks for understanding mental illness. One framework arises out of a psychosocial or psychodynamic model based on Freud’s theoretical speculations that has now evolved into many other psychological theories and models. This model attributes mental illness to environmental and psychosocial problems (nurture). The other model, biomedical or biological psychiatry, attributes mental illness to a chemical imbalance and genetics (nature). This chemical imbalance is thought to be due largely to either an excess or deficiency of neurotransmitters in the brain, and, thus, medication is thought to restore balance. The decade of the brain, 1990 to 2000, introduced a wave of studies based on the underlying premise that mental illness was a “brain disease” and should be treated as any other illness. This idea has been embraced by mental health providers, drug companies, as well as those diagnosed with a psychiatric disorder. Patient advocacy groups such as NAMI (the National Alliance on Mental Illness) believe that through understanding mental illness as a disease, the stigma associated with mental illness is reduced. However, a seminal research study found that this belief actually increases rather than decreases stigma and that people thought to have a brain disease are treated more harshly. Perhaps viewing, labeling, and diagnosing a person with a psychiatric disorder as “brain diseased” sets the person apart and further marginalizes the person as an “other.”

Stigma toward those with psychiatric disorders can be reduced through deepening our understanding of the effect of the environment on brain functioning. A majority of people served by public health, mental health, and substance abuse service systems have experienced repeated trauma since childhood and have been severely impacted by trauma. The increasing awareness of the prevalence and impact of trauma on people changes the paradigm from “what is wrong with the person” to “what has happened to this person.” The confluence of neurobiology, attachment theory, and infant development research with psychodynamic psychotherapy unites the disparate models of biological and psychosocial and is transforming the way we think about psychiatric disorders. Forging connections between psychological theories and neurobiology validates existing clinical practice as new knowledge continues to be generated. It is this meeting of biology with psychology that Freud envisioned more than 100 years ago.

### Neuroimaging

Since the early 1970s, imaging techniques have been developed that allow practitioners and researchers to map brain anatomy in exquisite detail and to estimate brain activity by measuring brain blood flow and metabolic rate. These imaging studies have suggested intriguing correlations between brain...
The Role of Genetics

Who we are and how we express ourselves through behavior depends on the complex influences of genetic and environmental factors on neural development and function. Since the early 1990s, the scientific knowledge base in genetics has grown exponentially and has created new tools to study the role of genetic inheritance in the development of mental illness. After three decades of research and thousands of publications, no definitive genetic links for specific psychiatric disorders have been identified. The complexity of mechanisms and systems involved in the development and sustainment of psychiatric disorders points to a complex interplay of psychological, sociocultural, developmental, and biological factors. The genetics of mental illness are much more complex than a simple single gene transmission based on linear thinking. Research using endophenotypes, which identify discrete physiological symptoms, suggests multiple pathways mediating diagnosis with one such study identifying 46 genes with links to the various deficits noted in schizophrenia. Both genetic vulnerability and environmental influences play significant roles in the development of mental illness. The term epigenetics has been coined to describe this interplay, that is, the environment selects, signals, modifies, and regulates gene activity. Heritable differences in gene expression are now thought to be not the result of DNA sequencing but on the encryption of experience that can be transmitted and alter behavior over generations.

The new wave of genetic studies is based on molecular genetics, that is, on the mechanism or process of molecular events (inherited or not) that influence the development of psychiatric disorders rather than mendelian genetics that describe the way in which genes modulate behavior and psychological traits. Some recent genetic studies have focused on genetic markers such as the presence of specific proteins in the brain postmortem of those who have suffered from a specific psychiatric disorder to those who did not have a psychiatric disorder. One such study on those who had bipolar disorder that is thought to be highly heritable concludes: “We have taken an innovative approach in correlating gene expression with genetic variation data from well-characterized postmortem brains and then combining with a large scale meta-analysis of genome-wide association studies. If replicated, this study could finally forge a link between gene expression and genome-wide association studies in a complex genetic disorder.” The problem, however, in such a postmortem study is that the protein found may be the result rather than the cause of the disorder.

The two psychiatric disorders that are thought to be the most heritable, schizophrenia and bipolar disorder, are now thought to share genetic roots. Significant epigenetic chemicals have been found in the genome of 22 pairs of identical twins diagnosed with either schizophrenia or bipolar disorder. That is, the twins did have identical DNA, but significant differences were noted in the gene activity caused by their environment. This is strong evidence that supports the hypothesis that epigenetic mechanisms may drive psychiatric disorders. In addition, genetically identical twins are only 50% concordant for developing schizophrenia. This means that 50% of the variance is attributed to environmental or other nongenetic contributions.

It is also important to note when considering the genetic research of psychiatric disorders that psychiatric diagnoses are not precise or definitive but are based on common characteristics of behavior, shifting criteria, and categories or subsets for various diagnoses. In order to conduct mendelian genetic studies, phenotypes must be identified, which are based on observable characteristics of a specific disorder. This is difficult because psychiatric diagnoses are best viewed as syndromes or a collection of symptoms rather than a discrete disease state. It is not possible to validate a psychiatric diagnosis with a physical examination or laboratory tests. This is particularly problematic for some diagnoses such as schizophrenia that has many different symptom clusters, that is, one person can receive the diagnosis of schizophrenia without having anything in common with another person with the same diagnosis. Without a reliable and valid diagnosis, mendelian genetic research is only speculative.

Abnormalities in a CT scan are not diagnostic of any particular mental illness; however, they suggest a brain-based problem. Structural abnormalities of the brain have been measured in people with schizophrenia, mood disorders, and dementias. An MRI used primarily for diagnosis of structural changes in the brain allows visualization of smaller lesions than the CT scan and distinguishes gray and white matter. Newer techniques measure brain function as well as structural changes through the fMRI, which detects blood flow in the brain. The MEG detects the minute magnetic fluctuations of regional brain activity. The basis of the PET is the brain tissue uptake of an infused radioactive substance. The tissue uptake of the substance depends on tissue type and metabolic activity. Labeled drugs can be infused to study neurotransmitter receptor activity or concentration in the brain. The SPECT is similar to PET but is less expensive and uses more stable substances and different detectors to visualize blood flow patterns. The SPECT is useful for diagnosis of cerebrovascular accidents and brain tumors.

A CT scan of the brain provides a three-dimensional view of brain structures that differentiates fine densities. Abnormalities in a CT scan are not diagnostic of any particular mental illness; however, they suggest a brain-based problem. Structural abnormalities of the brain have been measured in people with schizophrenia, mood disorders, and dementias. An MRI used primarily for diagnosis of structural changes in the brain allows visualization of smaller lesions than the CT scan and distinguishes gray and white matter. Newer techniques measure brain function as well as structural changes through the fMRI, which detects blood flow in the brain. The MEG detects the minute magnetic fluctuations of regional brain activity. The basis of the PET is the brain tissue uptake of an infused radioactive substance. The tissue uptake of the substance depends on tissue type and metabolic activity. Labeled drugs can be infused to study neurotransmitter receptor activity or concentration in the brain. The SPECT is similar to PET but is less expensive and uses more stable substances and different detectors to visualize blood flow patterns. The SPECT is useful for diagnosis of cerebrovascular accidents and brain tumors.
Recent animal and human studies strongly indicate that genetic factors of stress reactivity and a temperament toward reactivity may predispose one to a psychiatric disorder. Those who have a stronger, more persistent response to stressors tend to withdraw from stressful situations that have internalizing traits. These people may be inhibited and more fearful, thus predisposing the person to anxiety and depressive disorders. Likewise those whose temperament tends toward externalizing traits may be predisposed to develop psychopathology with symptoms of impulsivity, aggressiveness, and attentional difficulties. Caregivers who are not able to mediate arousal for their offspring with either of these traits are likely to exacerbate difficulties with affect and self-regulation that may lead to psychopathology.20

**The Stress–Diathesis Theory**

The stress–diathesis model of psychiatric disorders evolved from a recognition that genetics (diathesis) and environment (stress) both contribute to the development of psychiatric disorders.21 That is, that a person who is thought to have a genetic vulnerability encounters significant early life stressors such as childhood trauma or neglect, loss, or viruses, and these trigger the expression of the underlying condition. Thus, people who have less of a genetic predisposition will need more stressors to develop the illness. However, some disorders such as PTSD and phobias can be triggered by exposure to extreme stress in people who otherwise would not be vulnerable. There is some evidence that the most powerful predictor of psychosis and the diagnosis of schizophrenia is poverty.22 Thus, there are multiple determinants and correlates of causation for psychiatric disorders.

Large-scale epidemiological and case-controlled studies have found that trauma due to various reasons underlies a wide range of psychiatric disorders as well as medical illness.23–27 Most people, 55% to 90%, have experienced at least one traumatic event with an average of five traumatic events reported per person.23 A person’s response and the long-term sequelae of a disturbing event are highly individualistic and depend on a multitude of factors, some of which are the person’s age, developmental stage, coping skills, support system, cognitive deficits, preexisting neural physiology, and the nature of the trauma.

Adults who report significant traumatic experiences, such as an emotional, physical, or sexual abuse as children, show a graded positive response, that is, the more trauma experienced, the more both medical and mental illness occur later as adults. The incidence of mental health problems such as obesity, sexually transmitted diseases, alcoholism, severe and persistent mental illness, psychosis, substance abuse, eating disorders, anxiety, and depression has been significantly and positively correlated with what is termed “adverse childhood experiences” (ACE). A more recent prospective study confirms the ACE study and further found that those who were victims of maternal neglect and physical and sexual abuse were almost three times as likely to experience major depression by their early 30s.28 These study participants were at risk for high inflammation levels (high-sensitivity C-reactive protein level >3 mg/L) and clustering of metabolic risk biomarkers (overweight, high blood pressure, high total cholesterol, low high-density lipoprotein cholesterol, high glycated hemoglobin, and low maximum oxygen consumption levels). These physiological changes predisposed the person to develop cardiovascular disease and the risk for heart disease was doubled. Enduring emotional, immune, and metabolic changes result from exposure to adverse psychosocial experiences in childhood.

Researchers have found that the key pathway for these physiological changes is the complex bodily reactions to the stress response. Stress is differentiated from trauma in that trauma refers to events that render the person helpless, while stress refers to a state of burdened response to outside stressors, resulting in deterioration and dysfunction.29,30 Thus the degree of control that a person has over a stressor plays a key role in determining whether the event will lead to subsequent vulnerability to illness or resilience to stress. Stress responses are beneficial in mobilizing the body for action, but prolonged activation of the stress response particularly in early childhood leads to profound long-term physical changes. Early adversity has been found to alter the DNA in the brain through a process called methylation.31,32 Methyl groups affix genes that govern the production of stress hormone receptors in the brain that in turn prevents the brain from regulating its response to stress. Parental nurturing mediates this epigenetic response, but in the absence of nurturing, children have difficulties with attention and following directions. As teenagers, they are more likely to engage in high-risk behavior and, as adults, show increased aggression, impulsive behavior, weakened cognition, and an inability to discriminate between real and imagined threats.33

There is a growing recognition that the definition of trauma expands from what are traditionally considered traumatic events, such as natural disasters, terrorist activities, war, incest, physical abuse, car accidents, or other life-threatening events to include those things that occur often and to most people. The latter include emotional neglect or indifference, caregiver depression, chronic mother–infant misattunement, chronic loneliness, betrayals, significant loss, poverty, and many other life events that significantly impact the developing brain. Common stressful events such as relational problems, divorce, and loss of a loved one often do cause PTSD symptoms.33–38 Major and minor traumatic events are thought to underlie or contribute to wide range of psychiatric disorders and medical problems. These events interfere with information processing in the brain, and neural dysregulation disrupts adaptive processing. Healthy functioning is reflected in the optimal integration and coordination of neural networks in the brain: “When the brain is operating efficiently, multiple assemblies of neurons are firing in unison, and information is flowing freely from one area to another”33 (p. 19).

**Brain Development**

Complex physiological processes allow us to accumulate and distill experiences that involve energy use, metabolism, and
blood flow in the brain. The genome contains elements of the collective experience of our species with the degree of expression determined by critical developmental periods in tandem with the person’s experience and interaction with their environment. The brain has already started to develop in utero, and at birth the brain is relatively large compared to the infant’s body. The primary task of brain development is the sequential acquisition of networks of neurons. Sequential acquisition means that the brain develops from the bottom up with templates of neuronal networks laid down to form brain structures. The most rapid brain development occurs early in life with the brain tripling in size by 5 years of age, largely due to myelination.

The brain develops from the brain stem to the midbrain through limbic structures to the cortex, which is the last area to develop. Brain development consists of neurons and glial cells laying down interconnections with other neurons that guide self-regulation and executive functioning. With over 100 billion neurons and thousands of receptors per neuron, the complexity of the neuronal networks is unimaginable. The right brain develops first and is involved in processing social–emotional information, promoting attachment functions, regulating body functions and supporting the individual in survival and coping with stress. The lower brain structures are less plastic and less complex than the higher structures. Neuroplasticity refers to areas of the brain that are responsive to the environment and that can continue to change. The lower brain functions, such as the brain stem, are more fixed and less malleable, while the higher functions of the brain in the prefrontal cortex continue to develop throughout life. Since the right brain develops first and is involved with developing templates for relationships, one can easily see how important and enduring early attachment relationships are not only for emotional regulation but also in regulating the body.

Brain development is experience dependent, which means that the more the neuronal network is activated, the more likely the connection of the neural networks will be strengthened with the brain changing response to this neural activity. Thus, neurons that “fire together, wire together.” A stimulating environment facilitates a process called arborization where dendrite branching in neurons proliferates. Systems of neural networks interconnect with other systems of networks so that if one is activated others are triggered. After growth spurts, between 15 months and 4 years, between 6 and 10 years during prepuberty, and during middle adolescence, pruning occurs. Pruning is a process where unused neural connections are eliminated.

The brain develops in the context of the attachment relationship with the primary caregiver. The caregiver serves a regulatory function and assists the infant in regulating arousal levels and emotional states. The brain develops only in the context of a relationship with another developing brain. Intense emotional experiences arise in the attachment relationship, and these experiences become indelibly etched into the early developing brain and involve the processing of core affect. Core affects refer to those emotions that are hardwired from birth and include seeking, fear, rage, care, panic, sad, lust, and play. These emotions are rooted in subcortical neurobiological processes associated with autonomic changes that support actions. These core affects are modulated by higher brain structures that evolve through learning over time, that is, we learn to express or not express emotions depending on the situation and the circumstance. Emotions are rooted in bodily or visceral experiences and reflect a specific neurophysiological state.

In optimal development through interactions with others, one develops personality characteristics and coping strategies that are adaptive and play a fundamental role in regulation of the self. In order to survive, humans, like all mammals, must communicate with their caretaker and evaluate whether their environment is safe or not. Survival behaviors are associated with specific physiological states that are determined by emotional regulation. Through evolution, the nervous system has evolved a social engagement system that mediates attachment, the autonomic functions of the myelinated ventral vagus. This system is located in the medulla and provides a social and neural inhibitory function for the nervous system. When the infant gazes at the caregiver’s face, the infant will try to engage through facial expression and vocalization. This system, the ventral vagal, develops rapidly after birth to support attachment. This inhibitory system is parasympathetic and promotes calm states, thus inhibiting sympathetic activity. The other branch of the parasympathetic system is the unmyelinated vagal called the dorsal vagal complex and when activated is accompanied by a freeze response and immobilization in the absence of flight or fight options. The third system is the sympathetic nervous system that prepares the body for emergency and fight or flight. These opposing systems operate much like a brake and an accelerator. If the ventral vagal is utilized and fails to provide safety, the sympathetic nervous system is recruited first and then the dorsal vagal, which results in a parasympathetic freeze response. It is not until the age of 3 that affect regulation functions are developed by the ventral vagal system.

Healthy brain development is contingent upon early experience and sequential completion of critical windows of opportunity for establishing neural connections. Subsequent development is dependent upon this basic circuitry of neural networks for successful acquisition of language, regulation of emotions, as well as mediating other behaviors. For example, axonal connections between the limbic system and prefrontal cortex are established between 10 and 18 months of age, and these neural pathways play a crucial role in modulating arousal and emotional regulation. Research shows that children brought up in a chaotic or nonnurturing environment suffer neurological consequences that are long lasting and difficult to remediate. This validates developmental theories of Erikson, Piaget, Mahler, Bowlby, Freud, and others through providing a neurobiological basis for sequential completion of the stages of childhood.

**Information Processing**

The signaling of the neuron mediates all aspects of our life from sensory perception to control of movement, to the generation of thought, to memory, to the experience and expression...
of emotion. The brain is extraordinarily complex, divided into several distinct groups of functional neurons that are highly interconnected, and thus able to influence each other’s activity. Information processing emerges from the signaling properties between the synapses and occurs within nanoseconds. Neurotransmitters percolate across the synaptic space and bind to receptors in the cell walls changing the permeability of the membrane, and the resulting ion shift causes second-messenger molecules to direct the cell’s activities. Modulation of the receptors and the strength of the synapse between neural neurons determine what information will be transmitted and received. The neurotransmitters and receptors mediate the response of the action and synapse potentials. However, for people with trauma, brain injury, or degenerative changes, information processing and cognitive function may be impaired.

There are several information processing models that explain how information in the brain is transmitted and transformed. Perhaps the most well known is the adaptive information processing (AIP) model that was developed by Shapiro in 1995 through her development and observations of the effects of a psychotherapy called eye movement desensitization and reprocessing (EMDR). AIP posits that there is an inherent information processing system that usually processes experiences to a physiologic integrative state where information is taken in and learning can occur. These distributed information processing systems are throughout the brain and display synchronized oscillations, that is, neural network systems entrain (become as one) to each other via their action potentials. Oscillations are the electrical activity that results from the depolarization and repolarization that occurs during neural activity. This synchronization allows for the creation of neural temporal maps so that perception, memory, cognition, emotion, language, and sensations result from the interactions between these systems of neural networks.

Adaptive processing means that experiences are integrated into other neuronal networks or systems. When operating efficiently, memory is optimally stored in a way that allows for connection with other memory networks. Psychopathology is thought to result when there is a dysregulation that disrupts the integration of these neural networks. The more intense the arousal of the amygdala, the stronger the memory imprint, and the less likely that the experience is processed. Neuronal circuits connect the amygdala to the prefrontal lobe in the cortex that serves as the translator of the emotion so that amygdala activation can be modulated.

Perception is the final stage of information processing. Perception consists of the input of sensory information from the outside world and the processing of this information into meaning. All sensory information from the external world is transmitted to the thalamus and then projected to the somatosensory cortex and prefrontal association area. The prefrontal association area keeps track of where information has been put in long-term memory and is responsible for retrieving and then integrating memories with sensory input for decision making. For example, visual stimuli from the retina are transmitted to centers in the thalamus through the optic nerve; from there, it is relayed to the primary visual cortex in the occipital lobe and then to the visual association cortex, where the person understands the meaning. It is the conscious awareness of sensory stimuli that results in behavioral responses to the sensation.

**Neurochemicals**

Neurochemicals are messenger molecules and neurohormones that are key in mediating endocrine and behavioral responses to stress. These substances are protein chains and include hormones (i.e., endocrine system), neurotransmitters (i.e., autonomic nervous system), immune cells (immune system), and neuropeptides. Genes are turned off and on by these messenger molecules with more than 300 messenger molecules identified. Neurotransmitters transmit signals across the synapse and activate the receptors of the postsynaptic cell. Although there are over 40 different neurotransmitters, those that are the most familiar and important for psychiatric disorders are acetylcholine (Ach), dopamine (DA), glutamate, gamma-aminobutyric acid (GABA), norepinephrine (NE), epinephrine (E), and serotonin (5-HT). Neurotransmission involves several discrete steps: (1) the synthesis of a transmitter substance, (2) the storage and release of the transmitter, (3) binding of the transmitter to receptors on the postsynaptic membrane, and (4) removal of the transmitter from the synaptic cleft. The classic neurotransmitters include small-molecule transmitters and neuroactive peptides. These molecules typically are stored in vesicles in the presynaptic axonal terminal and released by the process of exocytosis.

Neurotransmitters are either “excitatory” or “inhibitory.” Excitatory neurotransmitters such as glutamate increase the probability that the target cell will fire an action potential by mediating the depolarization of the target cell. Excitatory transmitters serve as the body’s stimulants promoting wakefulness, energy, and activity through regulating many of the body’s most basic functions, including thought processes, higher thinking, and sympathetic (neuroexcitatory) activity. Inhibitory neurotransmitters such as GABA serve as the body’s natural tranquilizers, generally serving to induce sleep, promote calmness, and decrease aggression. Acetylcholine and norepinephrine have both excitatory and inhibitory receptors and can mediate sympathetic arousal and/or agitation, as well as parasympathetic calming. Thus, it is an oversimplification to rigidly call a neurotransmitter excitatory or inhibitory because it depends on their receptor site.

An outline of selected neurochemical response patterns in stress and potential psychiatric disorders is included in Table 22.1.

**Neurohormonal factors** mediate behavioral responses to stress. There is considerable evidence that regulation of corticotropic-releasing hormone (CRH) and the hypothalamic–pituitary–adrenal (HPA) axis is essential for adaptation to stress and that traumatic experiences early in life are particularly disruptive to these systems. Elevation of CRH long-term pathophysiological changes can occur due to trauma particularly
early in life. Research on child abuse victims has found that women who were abused had increased HPA axis and autonomic activity in response to stress compared to controls and smaller hippocampal volumes. Cortisol is released during the stress response and is an important hormone that contributes to increased arousal, vigilance, inhibition of growth and reproduction, and containment of the immune response. Excessive cortisol can have serious deleterious effects on all systems of the body and plays an important role in the formation, processing, and retrieval of memories. DHEA is another adrenal steroid released under stress along with cortisol. It is thought that DHEA facilitates learning and memory and appears to enhance cognition and performance under stress.

**Memory**

For the purpose of classification, memory can be classified as immediate, recent, or remote. Immediate memory is typically confined to the remembering of information for a period...
of several seconds to minutes (e.g., 7 to 10 digits of a telephone number). It is thought that these memories involve implicit information with respect to the ability to pay attention. Recent memory encompasses remembering something from minutes to days, while long-term memory, which lasts for years, is generally thought to result from actual structural changes in the synapses. For example, there might be an increase in the number of presynaptic structures responsible for neurotransmitter synthesis or release. Brain structures critical to the formation of memories include the amygdala, the hippocampus, the prefrontal cortex, and the cerebellum. 

Memory is stored in neural networks across the brain, and these connections are linked together and organized around associated emotions, thoughts, images, and sensations. These interconnected biochemical and neuronal networks serve as templates for future experiences depending on how the memory was perceived and stored in the brain. Pathways of neurons are forged by experience and continually revised by new and ongoing experiences depending on plasticity of the specific brain structure. Retrieval of information depends on the chemical state of the brain at the time of storage so that the memory is linked to the emotion surrounding the event at the moment that it occurred. This is termed “state-dependent learning.” Thus, memories are best remembered when the physiological state in which we learned the information matches the physiology of the present situation. Each emotional state has a specific template or physiological profile that is lined with its concomitant thought, image, and sensation. We slip in and out of various states of consciousness throughout the day depending on stimuli from our internal and external environment.

Behavior is altered by environmental cues that are processed through learning and memory. Learning changes the pattern of receptors in the information network. There are two forms of memory: implicit memory, which is largely unconscious and includes somatic, motor, emotional, and procedural memories, and explicit memory, which is involved with processing the factual knowledge of people, places, and things and its meaning. People with psychiatric disorders not only experience specific cortical dysfunctions but may experience difficulty in the proposed pathways for learning and memory.

Thought processes involve a pattern of stimuli from many parts of the nervous system at the same time and in a definite sequence. Each thought requires simultaneous input from portions of the cerebral cortex, the thalamus, the limbic system, and the reticular formation in the brain stem. The prefrontal association cortex processes information from many areas of the brain and is necessary to achieve thinking. It has the ability to keep track of bits of information and recall them simultaneously from working memory. This allows us to plan, set goals, and solve problems. Thoughts are expressed in the form of language through the functions of the left hemisphere, with Broca area in the frontal lobe for word formation and Wernicke area in the temporal lobe for language comprehension (Fig. 22.1).

One of the most important structures in the brain that processes memory is the hippocampus. This structure of the brain is not fully developed until between 16 and 18 months of age, thus accounting for the amnesia of infancy. It is here, deep in the limbic brain, where information from the neocortex is processed, transmitted, and integrated. The hippocampus is important for explicit memory, reality testing, and inhibition of the amygdala. Research has found that the size of the amygdala and hippocampus is significantly reduced for those who have been significantly traumatized. The excessive stimulation of the amygdala interferes with hippocampal functioning so that the ability to semantically describe the traumatic experience is impaired. This inability to integrate the traumatic memory into a coherent narrative may leave the person with images and sensations without the words, and/or there may only be a somatic memory of the experience. The decreased functioning and size of the hippocampus is thought to result in behavioral disinhibition and an inability to learn from experience.

Another important structure with respect to memory is that of the cerebellum, the largest structure in the brain.
The cerebellum is activated when information processing and semantic memory occurs. The cerebellum is important in memory because it allows for attention to be shifted rapidly, accurately, smoothly, and efficiently.35 See Figure 22.2 for brain structures important for memory and information processing.

### Trauma and the Brain

Since many psychiatric disorders are thought to result from aborted or dysregulated information processing due to trauma, it is important to understand how trauma affects the brain. Traumatic memories do not form a coherent narrative but persist as implicit, behavioral, and somatic memories.45 This is thought to be due to the massive influx of neurochemicals that flood the brain when significant trauma occurs. Information travels from the brain stem (locus ceruleus where norepinephrine is produced) through the thalamus to the amygdala to the hippocampus to the anterior cingulate and the orbitofrontal cortex (OFC), which activates the hypothalamic pituitary adrenal axis to initiate the stress response.28 The brain may react even before the OFC has a chance to react.

The sympathetic nervous system in response to neuronal networks triggers the classic stress response, and a complex wave of physiologic processes cascades in order to promote survival. This involves the autonomic, endocrine, and immune systems (HPA axis) and all the attending messenger molecules. The simultaneous activation of cortisol and norepinephrine may stimulate coping behaviors unless there is increased arousal in the presence of low glucocorticoid levels and then undifferentiated fight or flight occurs. Cortisol inhibits the release of norepinephrine and modulates arousal. However, prolonged release of cortisol results in the release of glutamate, which is neurotoxic to dendrites and neurons. This inhibits its removal from the synaptic space, thereby initiating long-term synaptic connectivity so that fewer glucocorticoid receptors are available. If arousal continues unabated, these neuronal changes alter the prefrontal cortex and hippocampus so that memory is impaired.

The physiologic information connected with the experience is matched against previous state-dependent memories that includes emotional, motor, and somatic components of a particular state of consciousness. Information processing is interrupted because of the massive influx of norepinephrine and cortisol so that processing cannot continue toward adaptive memory networks. The experience is etched into the brain as if to tell the person: “Don’t forget this, this is important!” As a consequence, traumatic memories are stored differently with each component of the memory fragmented, that is, the somatic part of the memory may be separate from the cognition, which may be separate from the emotion, which may be separate from the senses such as sight, sound, and so on. These types of memories are isolated from each other and from the self. For example, a person who has been in combat may have fragments of memory or flashbacks such as an image or sound that is disconnected from the thoughts about what the sensation is connected to.

The hyperarousal in the sympathetic system is balanced by the parasympathetic system, which shuts down the sympathetic system. The endorphins and oxytocin interfere with memory consolidation so that memories may be completely
IN SUMMARY
Because the brain integrates the processes of learning, memory, and emotions, symptoms may be somatic, cognitive, and/or emotional impairment or a combination of all these dimensions. People with psychiatric disorders and brain injuries often experience difficulty in the proposed pathways for learning and memory. These difficulties are likely to influence behavior and can result in significant problems in daily living and functioning in relationships and work. An increased understanding of the complex interactions among the different parts of the brain will assist in the development of more effective psychotherapies and more efficacious use of psychotropic drugs.

TYPES OF PSYCHIATRIC DISORDERS
After completing this section of the chapter, you should be able to meet the following objectives:
- Discuss underlying neuropathophysiology of schizophrenia.
- Cite the differences between the diagnostic criteria for depressive disorder according to the DSM-IV-TR and DSM-V classification.
- Describe the manifestations of panic disorder, generalized anxiety disorder, social phobia, and obsessive–compulsive disorder and the underlying pathophysiology of each.
- Describe the epidemiology of addiction disorders.

Schizophrenia
Schizophrenia is a chronic debilitating psychotic disorder with disorganized, positive, and negative symptoms. It results in marked impairment in functioning. It affects approximately 0.7% of the world’s population and is thought to occur in some form in all cultures. Schizophrenia affects a person’s thoughts, feelings, perceptions, and overall behavior while interfering with filtering of stimuli from the environment. Although the word schizophrenia means “splitting of the mind,” it should not be confused with “split personality.”

Alterations in speech patterns can include using invented words (neologisms), derailment (loose associations), tangentiality (inability to stick to the original point), incoherence (loss of logical connections), or word salad (groups of disconnected words). Frequently, people with schizophrenia lose the ability to sort and interpret incoming stimuli, which impairs the ability to respond appropriately to the environment. An enhancement or a blunting of the senses is very common in the early stages of schizophrenia. Sounds may be experienced as louder and more intrusive; colors may be brighter and sharper. In addition, a person with schizophrenia often experiences sensory overload owing to a loss of the ability to screen external sensory stimuli.

Although hallucinations and delusions occur in other psychiatric disorders such as bipolar disorder, these are hallmarks of schizophrenia. Delusions and hallucinations may be related to the inability of the person with schizophrenia to filter,
**Chart 22.1 Hallucinations**

Hallucinations are described as “sensory perceptions with a compelling sense of reality.” They can involve any of the five senses but are auditory or visual. For example, the person may hear voices that tell them they are bad and should be punished. Hallucinations should be differentiated from illusions, which are misinterpreted sensory perceptions that are stimulated by actual external stimuli. The pathophysiological process of hallucinations can occur at several levels. The disorder may originate at the end organ, occur during sensory transmission, or be based on abnormal cortical reception, perception, or interpretation.

Hallucinations can be classified in several ways, such as by the structure or function involved, the etiology, or the affected sense perception. Hallucinations that are classified according to etiology may occur as the result of disorders of brain structure or function (brain tumors, epilepsy, metabolic disorders), drug reactions, sensory deprivation, sleep deprivation, or psychotic disorders. The type and content of hallucinations often provides insight into their etiology. However, the most commonly used classification of hallucinations is based on the sensory perception involved (e.g., visual, auditory, olfactory, tactile). Within this system, hallucinatory experiences involving the visual system are the most clearly categorized. Several types of visual hallucinations are normal life experiences (e.g., images seen in a dream). Several ophthalmologic stimuli also are accompanied by visual hallucinations. Ocular phosphenes, which are produced by vigorous rubbing of the eye, are a form of visual hallucination. The Charles Bonnet syndrome is an organic disorder occurring in older adults that is characterized by complex visual hallucinations. It is associated with loss of vision and is seen in older adults with preserved intellectual function. Visual hallucinations associated with psychiatric disorders tend to be complex, may be enhanced by auditory hallucinations, and often lead to delusional beliefs.

Auditory hallucinations include misperceptions of sounds such as ringing and buzzing noises, music, and voices. Although they commonly occur in psychiatric disorders, particularly schizophrenia, they also occur in other disorders. Musical hallucinations featuring the perception of music without an external stimulus can be seen in disorders ranging from hearing impairment, especially in depressed older adult women, to temporal lobe lesions. When associated with brain pathology, the lesion is usually on the right side of the brain. Auditory hallucinations are commonly reported as part of the aura of epilepsy. Tinnitus, the perception of ringing, buzzing, or whistling sounds, is often the result of disorders of the inner ear. Withdrawal states, particularly from alcohol, are known to cause auditory hallucinations. A variety of psychiatric disorders are accompanied by auditory hallucinations, such as the sound of voices. Often the source of the sound, which is sensed as occurring within the head, is difficult to localize. The voice often comments on the person’s behavior and echoes his or her thoughts. Voices are rarely described as supportive; they are most often described as critical and negative in tone. Strategies of distraction used by people hearing voices include listening to music, especially through headphones, or snapping rubber bands on their wrists. In addition, keeping a record helps to identify hallucinatory precipitants and thus helps people avoid those situations that act as precipitants.

Hallucinations involving smell and taste are often the result of damage to the olfactory bulb. Tumors at the base of the brain that extend into the olfactory cortex can produce olfactory hallucinations. People with migraine headaches may also experience an aura consisting of olfactory or gustatory hallucinations.

**Chart 22.2 Delusions**

Delusions are characterized by a false belief and the persistent, unshakable acceptance of the false belief. In contrast to hallucinations, which are abnormalities of perception, delusions are abnormalities of thought. Delusions are formed from and colored by a person’s background, including personal, family, and social experiences; educational background; and cultural (including religious) influences. Delusional thinking may include, among others, delusions of persecution (e.g., believing one’s self or property is being threatened), influence (e.g., believing thoughts can move through radio or atomic rays), ill health, grandeur (e.g., believing oneself to be a great person, such as the King of England), poverty, and possession (e.g., believing one’s body is possessed by God or some great power).

The causes or mechanisms underlying delusional thinking are unclear. It has been suggested that delusional thinking is the product of repeated stress, rather than a disorder based on a single, acute situational problem. Interestingly, delusions have been associated with conditions that produce sensory deprivation, such as hearing loss. In one study, older adults with late-life psychoses that included paranoid symptomatology were more likely to have moderate and severe hearing loss than control subjects.
interpret, and respond appropriately to stimuli. With respect to hallucinations, auditory hallucinations are especially common. In these cases, the person sees and hears things that are not in the external world but nevertheless are very real phenomena to the person experiencing them. Hallucinations may represent the end of the spectrum of increasing intensity of sensual stimuli. Auditory hallucinations range from simple repetitive sounds to many voices speaking at once. Sometimes the voices are pleasant, but often they accuse and curse. When visual hallucinations occur, they usually are in conjunction with auditory hallucinations.\(^{10,42}\)

Delusions are false ideas believed by the affected person that cannot be corrected by reason. They range from simply believing that people are watching them (ideas of reference) to beliefs that they are being punished and/or manipulated by others (delusions of paranoia). Delusions of being a historical figure (e.g., Jesus Christ or the President) also are common and are called grandiose delusions. Sometimes the delusions include a belief that the affected person is able to control others with his or her thoughts.\(^{42}\) The negative symptoms of schizophrenia reflect the absence of normal social and interpersonal behaviors and include aloxia (tendency to speak very little), avolition (lack of motivation for goal-oriented activity), apathy, affective flattening (lack of emotional expression), inappropriate affect, and anhedonia (an inability to experience pleasure in things that ordinarily are pleasurable). Some people with schizophrenia have a blunted response to pain. Negative symptoms are the most difficult to treat and often are severe and persistent between acute episodes of illness.\(^{10}\)

Another component of schizophrenia is referred to as disorganized behavior.\(^{42}\) This may manifest as aggression, agitation, catatonic excitement (hyperactive, purposeless activity with abnormal movements such as grimacing and posturing), echopraxia (imitation of another person’s movements), regressed behavior, stereotypy (repetitive, idiosyncratic movements), hypervigilance, and waxy flexibility (posture held in odd fixed position for extended periods of time). These three dimensions, positive or psychotic symptoms, negative symptoms, and behavioral disorganization, are used in evaluating the neurocognitive impairment that occurs with schizophrenia. Although cognitive tests are challenging for many people with schizophrenia, those in remission do better with the greatest deficits on tasks such as verbal memory, performance IQ, and coding tasks.\(^{46}\)

**Neurophysiology of Symptoms**

Recent research and data concerning schizophrenia present a complex image of brain dysfunction with alterations in brain structures, biochemical variations, and functional disturbances. The exact pathogenesis of schizophrenia is unknown. No single lesion in the brain appears to be specific to schizophrenia or to the brain of all people with schizophrenia. With the advent of neuroimaging techniques in the 1960s, it became possible to document what had long been suspected: that schizophrenia was associated with brain abnormalities. These abnormalities include reduced dendritic arborization of pyramidal neurons in the prefrontal cortex; arrested migration of hippocampal neurons; enlargement of the lateral and third ventricles; a reduction in frontal lobe, temporal lobe, and amygdala; and diminished neuronal content in the thalamus.\(^{10,46,47}\) Schizophrenia also is characterized by reduced metabolic activity in the frontal cortex on PET scan. Functional abnormalities also occur in the temporal and subcortical structures.\(^{46}\) There are also thought to be problems with the development and function of cortical networks and the pruning of synaptic connections in adolescence. In addition, dysfunctions in coordinated neural oscillatory activity have been found for schizophrenics that may contribute to the breakdown of large-scale cortical networks.\(^{46}\)

Additional anatomic findings include changes in the density of dopamine (D\(_2\)) receptor sites. With the finding that effective antipsychotic drugs are dopamine antagonists and that dopamine-releasing agents such as amphetamine can cause psychosis, the “dopamine hypothesis” was developed. This hypothesis proposes that the symptoms of schizophrenia are due to dopaminergic overactivity.\(^{10,39}\) Thus, higher levels of dopamine in the limbic system are thought to account for the positive symptoms of schizophrenia, while the negative symptoms reflect a deficiency of dopamine in the prefrontal cortex. However, it is possible that the increased density of dopamine receptors found in some studies is related to the effects of antipsychotic drugs. Other neurotransmitter changes implicated in the development of schizophrenia include a decreased activity of glutamate through dysfunction of its N-methyl-D-aspartate receptor.\(^{46}\) Many of the symptoms of impaired cognition seen in schizophrenia are thought to be tied to deficits in GABA. Lower production of the protein has been found in the dorsolateral prefrontal cortex and may be a consequence of mRNA dysfunction.\(^{46}\) Serotonin is also theorized to play a part. Atypical antipsychotics, which antagonize serotonin receptors, have been found to modulate the synthesis and release of dopamine in certain areas of the brain. Problems with oxytocin signaling in the amygdala are also being studied as a cause of deficits in social and emotional processes.\(^{30}\) These changes are tied to potential problems in appraising emotional salience and creating social narratives.

**Treatment**

The goals of treatment for schizophrenia are to induce a remission, prevent a recurrence, and improve behavioral, cognitive, and psychosocial functions. Early intervention programs are associated with a better treatment response.\(^{46}\) This has led to some children and adolescents who are considered high risk, that is, those who have problems in motor and neurologic development, deficits in attention and verbal short-term memory, poor social competence, positive formal thought disorder–like symptoms, and severe instability of early environment,\(^{42}\) to be given prophylactic antipsychotics. This practice raises ethical as well as treatment issues.
Schizophrenia is considered a chronic illness with remissions and exacerbations. For the person living with schizophrenia, the goal is recovery. According to the Substance Abuse and Mental Health Services Administration of the federal government, “mental health recovery is a journey of healing and transformation enabling a person with a mental health problem to live a meaningful life in a community of his or her choice while striving to achieve his or her full potential.” The implications and reality are that outcomes from this illness are varied with some people functioning at a much higher level than originally thought possible. However, hospitalization may be indicated if the person is a danger to self or others, is unable to provide basic care for self, or refuses to eat or drink.

Psychosocial interventions, which include patient and family education, housing support, vocational rehabilitation, social skills training, family interventions, cognitive–behavioral therapy, and cognitive–behavioral training, have been found to be effective for many people with schizophrenia. Psychosocial interventions are important to help people learn about and live successfully with their illness. Case management is also an important component for people with schizophrenia and includes assistance with housing, employment, or disability benefits, socialization, and co-occurring illnesses. Family members may need assistance in learning about the illness and the best ways to support each other and their family member with schizophrenia.

Pharmacological treatment with antipsychotics is often helpful particularly with the positive symptoms of schizophrenia (delusions, hallucinations, agitation, thought broadcasting, loose associations, and suspiciousness). Both typical and atypical antipsychotic drugs address these positive symptoms. The negative symptoms of schizophrenia respond more favorably to the atypical antipsychotic drugs (e.g., olanzapine, ziprasidone). Often antipsychotics are combined with benzodiazepines or antiparkinson agents during the acute phase of treatment to reduce the risk of extrapyramidal effects from large doses of antipsychotic agents. Both categories of drugs exert their effect by blocking dopamine receptors, although the atypical antipsychotics have a more refined blockade action. The atypical antipsychotics also exert some of their effects through blockade of serotonin (5-hydroxytryptamine [HT]) receptors. Treatment with atypical or second-generation antipsychotics, particularly Zyprexa and clozapine, has been implicated in the development of metabolic syndrome. Often there is a rapid weight gain upon initiation of treatment during the first year, and obesity, insulin resistance, hypertension, high triglyceride level, and low HDL cholesterol levels develop. Maintenance of pharmacotherapy is difficult for these reasons but also because of the cost of the medications and the side effect profile. The typical or first-generation antipsychotics, Thorazine and Haldol, can cause extrapyramidal symptoms (EPS), which includes parkinsonian-like symptoms. These symptoms are thought to be caused by the blockade of D2 receptors in the basal ganglia, which disrupts the balance of acetylcholine and dopamine in this area of the brain. Treatment for EPS is with an anticholinergic drug, such as Cogentin, that decreases acetylcholine activity.

**Mood Disorders**

Mood disorders are relatively common, but only half of those who need treatment are diagnosed and treated. The *DSM-IV-TR* includes major depression, dysthymia, and bipolar (manic–depressive) disorders within the diagnostic category of mood disorders. The *DSM-V*, however, has separate diagnostic categories for depressive disorders versus bipolar and related disorders. Overall the lifetime prevalence for mood disorders in the United States is 20.8% with the prevalence of major depression among women double that in men. In addition, the incidence of depression and bipolar disorder appear to be increasing. Prevalence of depression is higher in people from families with a history of mood disorders than in the population at large. Mood disorders are thought to occur with equal prevalence among races, although it is more frequently misdiagnosed as schizophrenia among nonwhite populations. Depression rates are also higher among people living in or near poverty.

The *DSM-IV-TR* diagnostic criteria for a major depressive episode include the simultaneous presence of five or more symptoms such as depressed mood, anhedonia (diminished pleasure), weight loss or weight gain, insomnia or hypersomnia, agitation or slowing down, fatigue, feelings of worthlessness, lack of concentration, and recurrent thoughts of suicide during a 2-week period, and these must represent a change from previous functioning. Depression must be differentiated from grief reactions, medication side effects, and sequelae of medical illnesses. It should be noted, however, that depression often co-occurs with physical illnesses, notably myocardial infarction. It is estimated that 50% of people hospitalized with coronary artery disease have some depressive symptoms, with up to 20% developing major depression. Depression negatively impacts prognosis, affecting both behavioral and physiologic aspects of recovery, and increases the risk of death. In addition, other medical illnesses are associated with depression and include endocrine disorders, cardiovascular disease, neurologic disorders, autoimmune conditions, viral or other infectious diseases, certain cancers, and nutritional deficiencies.

Bipolar disorder is diagnosed on the basis of the pattern of occurrence of manic, hypomanic, and depressed episodes over time that are not due to medications or other therapies. The frequency, duration, and severity of the manic or depressive periods are unique to each person. Mania, particularly in its severe delusional forms, also needs to be differentiated from schizophrenia or drug-induced states.

**Major Depression and Dysthymia**

Depressive disorders are commonly divided into two categories: major depressive disorder (characterized by a persistent unpleasant mood) and dysthymia (characterized by chronic mild depressive symptoms). Depression can vary in intensity and often is recurrent. The average age of (onset of) depression is the mid-30s. However, the age of onset of depression has been decreasing. The earlier and more frequent the onset...
of symptoms, the more likely it is that the affected person will require medications for symptom relief. Depression in older adults often appears with an element of confusion and often is left untreated. A first episode of depression that occurs after 65 years of age can be a precursor to dementia and should precipitate both assessment and treatment of the depression, as well as a thorough evaluation for dementia. Early intervention often greatly retards the progression of dementia, maintaining the person’s independence and quality of life.

Major depressive disorder is characterized by the following: depressed mood, anhedonia (inability to experience pleasure), feelings of worthlessness or excessive guilt, decreased concentration, psychomotor agitation or retardation, insomnia or hypersomnia, decreased libido, change in weight or appetite, and thoughts of death or suicidal ideation.

Depression has various subclassifications distinguished by symptom patterns. Depression with melancholic features is characterized by depression that is worse in the morning, insomnia with early morning awakening, anorexia with significant weight loss, psychomotor retardation or agitation, excessive or inappropriate guilt, loss of interest in activity, inability to respond to pleasurable stimuli, and a complete loss of capacity for joy. The symptoms of atypical depression are opposite those of melancholic depression. It is characterized by a depression that becomes worse as the day progresses, overeating, and hypersomnia (excessive sleep). Depression with psychotic features involves the presence of delusions or hallucinations that may or may not be mood congruent. The classification of depression with catatonic features is applied when symptoms include excessive mobility or motoric immobility, extreme negativism, repetitive speech, and peculiar voluntary movements. The chronic specifier is applied if symptoms of major depression persist for 2 or more years. A postpartum specifier is included if the onset is within 6 weeks of childbirth. Most women experience some mild letdown of mood in the postpartum period. For some, the symptoms are more severe and similar to those seen in serious depression, with increased emphasis related to the infant (obessive thoughts about harming it or an inability to care for it). When psychotic symptoms occur, there is frequently associated sleep deprivation, volatility of behavior, and manic-like symptoms. Biologic vulnerability with hormonal changes and long-lasting changes in neuronal function. The more frequent a person has a shift in mood, cycling into either mania or depression, the easier it becomes to have another episode. There is evidence that many psychiatric disorders, not just bipolar disorder, are subject to this phenomenon. The better the control of the illness and the fewer cycles a person has, the better his or her quality of life is likely to be.

**Bipolar Disorder**

The prevalence of bipolar disorder is approximately 2.6% in the population at large with 82.9% of these cases classified as severe. Approximately 20% to 40% of adolescents who present with major depression develop bipolar disorder within 5 years. The average age of onset of bipolar disorder is the mid- to late 20s. However, the age of onset of bipolar disorders has been decreasing. Men present more often with the manic phase in the initial episode, whereas women more often have the depressed phase as the initial episode. Bipolar depression, or manic–depressive disorder, also has multiple subclassifications, all of which are usually characterized by episodes of elation and irritability (mania) with or without episodes of depression.

Although mania without associated depression (unipolar mania) can occur, it is rare. Mania, in people with bipolar disorder, can be precipitated by antidepressant medications and the somatic therapies used to treat depression, such as electroconvulsive therapy.

The clinical manifestations of mania include decreased need for food and sleep, labile mood, irritability, racing thoughts, high distractibility, rapid and pressured speech, inflated self-esteem, and excessive involvement with pleasurable activities, some of which may be high risk. In its minor forms, the subjective experience of mania can be quite pleasurable to the person, with a heightened sense of well-being and increased alertness. The severity of manic symptoms runs the gamut from a condition called cyclothymia, in which mood fluctuates between mild elation and depression, to severe delusional mania. Mania may begin abruptly within hours or days or develop over a few weeks. Mixed states with features of both mania and depression present at the same time often are not well recognized. Bipolar episodes, left untreated, become more severe with age.

Rapid cycling is said to occur when a person has four or more shifts in mood from normal within a 1-year period. Women are more likely than men to be rapid cyclers. Rapid cycling is thought to be due to kindling. Kindling is a hypothesized phenomenon in which a stressor creates an electrophysiologic vulnerability to future stressful events by causing long-lasting changes in neuronal function. The more frequently a person has a shift in mood, cycling into either mania or depression, the easier it becomes to have another episode. There is evidence that many psychiatric disorders, not just bipolar disorder, are subject to this phenomenon. The better the control of the illness and the fewer cycles a person has, the better his or her quality of life is likely to be.

**Neurophysiology of Symptoms**

In some cases of familial major depressive disorder and bipolar disorder, PET and MRI studies have demonstrated a reduction in the volume of gray matter in the prefrontal cortex, with an associated decrease in activity in the region. Structural imaging studies have consistently found abnormalities in the subgenual prefrontal cortex in people with familial bipolar disorder, a region related to responses to emotional experiences. Clinical studies have suggested that this area of the brain is important for mood states and has extensive connections with the limbic system. Physiologically, there is
evidence of decreased functioning in the frontal and temporal lobes, although it is not known if this is a cause or an effect of depression because the activity returns to normal with the resolution of the symptoms.\textsuperscript{58,59} In addition, smaller hippocampal volumes have been reported in people who have depression and have suffered early abuse.\textsuperscript{38} The amygdala tends to have increased blood flow and oxygen consumption during depression. Unlike those areas where function returns to normal with the resolution of depression, the amygdala continues to be excessively active for 12 to 24 months after the resolution of depression. It is hypothesized that relapse into depression is more likely to occur if medications are decreased or stopped before the amygdala returns to normal functioning. Neurologic disorders of the limbic system and basal ganglia are also involved in the development of mood disorders.\textsuperscript{10}

A number of neurotransmitters, serotonin and norepinephrine in particular, are implicated in depression.\textsuperscript{39,42} The biogenic amine hypothesis suggests that decreased levels of these neurotransmitters in the synaptic cleft, due either to decreased presynaptic release or decreased postsynaptic sensitivity, is the underlying pathologic process in depression. The hypothesis is derived from the fact that drugs that depleted brain serotonin and norepinephrine cause depression, and drugs that increase brain levels of norepinephrine and serotonin decrease depression. Dopamine activity has also been implicated in mood disorders, with decreased dopamine sensitivity, is the underlying pathologic process in depression. It is hypothesized that relapse into depression is more likely to occur if medications are decreased or stopped before the amygdala returns to normal functioning.

Disturbances in the function of the HPA axis also may play a critical role in depression. Early life stressors such as neglect or trauma produce chronically elevated levels of cortisol.\textsuperscript{39} Abnormally high CRH levels in the cerebrospinal fluid have been linked to major depression and PTSD. In the general population, cortisol levels usually are flat from late in the afternoon until a few hours before dawn, when they begin to rise. In people with depression, cortisol levels spike erratically over the 24 hours of the day. Cortisol levels return to the normal pattern as depression resolves. In 40% of those diagnosed with depression, hypersecretion of cortisol is resistant to feedback inhibition by dexamethasone, indicating a dysfunction of the HPA axis.\textsuperscript{39,42} About 5% to 10% of people with depression have a decrease in thyroid function, in which case the person is less likely to have a vigorous response to medical intervention.

Alteration in the sleep–wake cycle is common in many mental illnesses and often is one of the prodromal signs of relapse. Researchers have found that the normal sleep cycle is reversed in depression. People with depression often have what is called dream pressure sleep. The depressed person falls into light and dream-state sleep early in the sleep cycle and reaches deep stage 4 sleep only late in the sleep cycle. This finding helps explain why many inpatients report they did not sleep all night and the staff reports that the person was asleep all night. Although the sleep cycle usually reverts to normal after the resolution of the depression, it may not be completely normal for weeks to months. Decreasing or halting medications before the sleep disturbances resolve may lead to a relapse of depressive symptoms. Fatigue and hypersomnia are common among people with depressive disorder, and people who complain of chronic fatigue are at risk for development of major depressive disorder.\textsuperscript{61}

Circadian rhythms also are an area of serious research interest. A specific type of depression known as \textit{seasonal affective disorder} (SAD) is triggered for people in the winter by the shortening of daylight hours as fall commences, with symptoms of depression usually resolving in the spring when daylight hours again lengthen. Circadian rhythm considerations are also critical in symptom management for persons with bipolar depression. One of the fastest ways to precipitate a manic episode is for the person to stay up all night. It is not unusual for a first manic episode to occur when someone “pulls an all-nighter” studying for final examinations. People with bipolar disorder should have a fairly rigid schedule for sleeping and awakening if cycling is to be minimized. Although exercise is important, the person with bipolar disorder should exercise before midafternoon to prevent the normal increase in metabolic rate from disrupting the sleep cycle.

\textbf{Treatment}

Psychopharmacology has become a popular and effective treatment for mood disorders. Antidepressants alleviate depressive symptoms by increasing the activity of norepinephrine and serotonin at postsynaptic membrane receptors. The most widely used antidepressants are the serotonin reuptake inhibitors (SRIs), which inhibit the reuptake of serotonin at the presynaptic space. Formulations of the SRIs vary and target different neurotransmitters. These include the selective serotonin reuptake inhibitors (SSRIs; \textit{e.g.}, fluoxetine [Prozac], fluvoxamine [Luvox], paroxetine [Paxil], citalopram [Celexa]), the serotonin antagonist and reuptake inhibitors (SARIs; \textit{e.g.}, nefazodone [Serzone]), and the serotonin and norepinephrine reuptake inhibitors (SNRIs; \textit{e.g.}, venlafaxine [Effexor], duloxetine [Cymbalta]). The atypical antidepressants affect serotonegic and noradrenergic neurotransmission.

The tricyclic antidepressants (TCAs; \textit{e.g.}, amitriptyline [Elavil], imipramine [Tofranil], nortriptyline [Aventyl, Pamelon]) block the reuptake of serotonin and norepinephrine by the presynaptic membrane, whereas the SRIs inhibit the reuptake of serotonin. The monoamine oxidase (MAO) inhibitors are used less often because of their side effect profile and specific dietary restrictions. MAO inhibitors (\textit{e.g.}, phenelzine [Nardil], tranylcypromine [Parnate]) increase the concentration of serotonin and norepinephrine by reducing the degradation of these neurotransmitters by MAO.

Electroconvulsive therapy (ECT), a procedure that electrically stimulates a generalized seizure, is a highly effective
treatment for depression in people with severe depression.\textsuperscript{62,63} Because the motor component of the seizure does not contribute to the therapeutic effects of the treatment, modern ECT is always given under general anesthesia with complete muscle relaxation. On an average, six to eight treatments are given at 2-day intervals over a period of 2 to 4 weeks.

Phototherapy, or light therapy, uses artificial light to influence the production of melatonin and the function of the catecholamine systems. It is often a first-line treatment for depression associated with seasonal changes, such as SAD.\textsuperscript{64}

Lithium and several anticonvulsant agents are used in the treatment of bipolar depression. Lithium’s exact mechanism of action is unknown. It is known to inhibit the accumulation of cyclic adenosine monophosphate (cAMP) and may down-regulate second-messenger systems that are associated with cAMP-linked receptors.\textsuperscript{10} Anticonvulsant agents, especially carbamazepine and valproate, have also proved to be effective for the treatment of bipolar depression. However, the mechanism by which these drugs act is not completely understood. One theory for the mechanism of action proposes blocked effects of the excitatory amino acid glutamate.\textsuperscript{10}

Newer therapies, such as vagal nerve stimulation and transcranial magnetic stimulation, are being considered as treatment for depression that does not respond to pharmacologic interventions. The effectiveness of these treatments is still unclear.\textsuperscript{65,66}

Psychotherapy is included in most practice guidelines for depression and is an important component of therapy for people and families with major depressive disorders. People and families can learn how to deal with stressful life events and heal disrupted interpersonal relationships. Those with the most efficacy include interpersonal therapy, cognitive–behavioral therapy, and problem-solving therapy.\textsuperscript{67} In addition, a meta-analysis of 23 studies found that short-term psychodynamic psychotherapy resulted in large depression symptom reductions, which were maintained in 1-year follow-up.\textsuperscript{68} Individual STPP was found as efficacious as other psychotherapies at posttreatment and in follow-up. It is generally agreed that without psychotherapy in tandem with medication, long-term results are difficult if not impossible to maintain.

Unfortunately, many people with bipolar disorder do not believe they need treatment, particularly during the manic phase of the illness, and tend to self-medicate with alcohol or recreational drugs. It is not unusual for people with bipolar depression to be diagnosed with substance abuse. When in the manic phase, they often feel exceptionally creative and talented. When helping people make the decision to enter treatment, it is important that they understand the treatment will not stop their creativity.

### Anxiety Disorders

Anxiety disorders are characterized by intense fearfulness that occurs without a precipitating potentially dangerous event, accompanied by subjective as well as objective manifestations. Just as grief is a normal response to personal loss, anxiety is a normal response to threatening situations. Anxiety disorders are the most prevalent of the psychiatric disorders. Anxiety disorders affect approximately 28.8\% of all people, women more often than men.\textsuperscript{60} Women are 60\% more likely than men to experience an anxiety disorder over their lifetime.

A key component of anxiety disorders is increased fear accompanied by subjective as well as objective manifestations. The subjective manifestations range from heightened awareness to deep fear of impending disaster or death. The objective manifestations, which occur with activation of the sympathetic cascade through the HPA axis, include restlessness, sweating, palpitations, an increase in heart rate and blood pressure, dry mouth, and a desire to run and escape. According to the \textit{DSM-IV-TR} classification system, anxiety is subdivided into five types, depending on clinical characteristics and response to pharmacologic agents: panic disorder, PTSD, generalized anxiety disorder, social phobia, and obsessive–compulsive disorder (OCD).\textsuperscript{63} The new \textit{DSM-V} places PTSD in the diagnostic category of trauma-related disorders and separates out OCD into its own diagnostic category.\textsuperscript{63} PTSD is covered in Chapter 9. Therefore, this discussion includes panic disorder, generalized anxiety disorder, OCD, and social phobia.

### Panic Disorder

Panic disorder is a disabling condition seen in people in the primary care settings.\textsuperscript{70,71} The disorder has been reported to occur in 3\% to 8\% of people seen by primary care physicians. The disorder is twice as common in women as men, and there appears to be an apparent bimodal distribution in age of onset, with one peak in late adolescence and a second peak in the mid-30s.\textsuperscript{70} The diagnosis of panic disorder may be made more difficult by the presence of symptoms such as chest pain and shortness of breath that also are associated with potentially more serious conditions. Often those with panic attacks initially are seen in emergency room settings with the person convinced that they are experiencing a heart attack.

People with panic disorder typically have attacks characterized by neurologic symptoms (dizziness or lightheadedness, paresthesias, fainting), cardiac symptoms (tachycardia, chest pain, palpitations), respiratory symptoms (shortness of breath, feeling of smothering or choking), sweating, nausea or abdominal distress, and psychological symptoms (feelings of impending doom, fear of dying, and a sense of unreality). Panic attacks, which are unexpected and not related to external events, usually last 15 to 30 minutes, but sometimes continue for an hour. Comorbidities are common with 91\% of those with panic disorder also having another psychiatric disorder.\textsuperscript{10} Depression, other anxiety disorders, and substance abuse disorders are not uncommon. Agoraphobia is closely associated with panic disorder in that people with agoraphobia avoid any situation in which it would be difficult to get help and are fearful of feeling fear. It is thought that the higher incidence of substance abuse disorders results from an effort to self-medicate to ameliorate the anxiety. Environmental and stressful life events appear to be involved in the causation of panic attacks.\textsuperscript{71,72} Children who suffer separation anxiety often
develop panic disorder as adults. In addition, early traumas such as socioeconomic disadvantages and a history of physical or sexual abuse are associated with the development of panic disorder.66,67 Approximately 80% of people with panic disorder report major life stressors during the previous 12 months.71 Significantly higher rates of panic disorder occur among Whites compared to African American, Asians, and Latinos.73

Neurophysiologic studies suggest that the attacks may result from an abnormally sensitive “fear network” that is centered in the amygdala and involves interactions with the prefrontal cortex.10 Projections from the amygdala to hypothalamic and brain stem sites account for many of the observed signs (e.g., sweating, increased heart rate, respiratory responses) of the fear response.10 Responses to medications indicate that multiple mechanisms and neurotransmitters are involved in initiating the panic attack. Norepinephrine, serotonin, and GABA are the three neurotransmitters most associated with this disorder.10 People experiencing panic attacks have been found to have somewhat lower levels of serotonin than do people with no known mental illness, but the mechanism for that decrease is not known.

Treatment includes the use of behavioral, psychological, and drug therapies. All antidepressants, except bupropion, are effective in the treatment of panic disorders. There is growing evidence in the greater effectiveness of SSRIs in the treatment of panic, but full response to medication can take 12 or more weeks.10 Many people may require the use of more than one class of medication for the management of panic attacks. However, treatment is most effective when psychotherapy focused on cognitive and behavioral changes is included as part of a comprehensive program. If inadequately treated, people with panic disorder frequently develop phobias, particularly agoraphobia, that can be so debilitating that the person cannot leave his or her house.10,42

**Generalized Anxiety Disorder**

In 1980, generalized anxiety disorder was first recognized as a separate entity from panic disorder in the DSM-III. Since then, the diagnostic criteria have been sharpened in an attempt to improve the ability of practitioners to discriminate the disorder. The central characteristic of generalized anxiety disorder is prolonged (>6 months), excessive worry that is not easily controlled by the person. The characteristics of the disorder include muscle tension, autonomic hyperactivity, and vigilance and scanning (exaggerated startle response, inability to concentrate). Neurotransmitter dysregulation is thought to underlie all anxiety disorders. The neurotransmitter GABA and its receptors are associated with symptoms of anxiety, that is, too little GABA increases anxiety symptoms as well as too much norepinephrine and glutamate. The benzodiazepines (e.g., chlordiazepoxide, diazepam) are particularly effective drugs in treating this disorder. These drugs increase the activity of the GABA subunit receptor, which increases the flow of chloride ions across the cell membrane, hyperpolarizing the membrane and thus inhibiting firing of target cells.10 Buspirone is another effective medication for treating generalized anxiety disorder, but may take up to 2 weeks to show antianxiety effects and up to 6 weeks for maximum benefits. SSRIs are also used in the treatment of generalized anxiety disorder, and it is thought that they result in limbic, paralimbic, and frontal hyperactivity normalization. Other medications used in the treatment of generalized anxiety disorder include other antidepressants (tricyclic and atypical antidepressants) and β-adrenergic blockers, the latter of which block the symptoms of anxiety rather than treating the anxiety disorder itself.

**Obsessive–Compulsive Disorder**

OCD is an anxiety disorder characterized by recurrent obsessions (repeated thoughts) and compulsions (repeated acts).5,6 To be defined as compulsive, the behavior (activities such as hand washing, ordering, or checking or mental activities such as praying, counting, or repeating words) must be repeated excessively, and the repetition must not be related to any environmental condition. These behaviors are time consuming or distressing to the person. Usually, the person experiencing the symptoms recognizes that the rituals are unreasonable. For instance, the person may have to recheck the stove many times before she is able to leave for work or may have to check the stairwells at work repeatedly for debris to ensure that no one is injured. It is estimated that there is lifetime prevalence of 2% in the United States with the average age of onset approximately 19 years old.74,75 OCD often is underdiagnosed in children because it may appear as a behavior problem with angry outbursts that are impulsive and thus may be confused with attention deficit disorders or poor school performance.10,42 This disorder is found with equal frequency among men and women, and there is a higher prevalence among family members.75 Comorbidities are common; Tourette syndrome and OCD frequently occur together.76

Although the neurophysiology of OCD remains under investigation, the general anatomic model suggests dysfunction of the prefrontal cortex and structures of the basal ganglia, particularly the caudate nucleus and globus pallidus.77 More recent studies using neuroimaging techniques have found increased activity in the orbitofrontal cortex, the anterior cingulated cortex, and the caudate nucleus.78 Increased glucose metabolism in the brain has also been identified in these areas.79

Diagnosis of OCD is based on the history and clinical observation. Treatment methods for OCD include behavioral therapy (involving exposure to feared situations and the prevention of compulsive behavior), cognitive therapy (in which maladaptive thoughts are challenged), and specific medications. About 50% to 60% of people with OCD respond to SSRIs, but often require a higher dose than that prescribed for treatment of depression. The TCA clomipramine is sometimes prescribed if there is a poor response to SSRIs, and an atypical antipsychotic may be added in severe cases. This disorder is particularly amenable to cognitive–behavioral therapy, and for most people with OCD, combining cognitive–behavioral therapy with medication is the best approach.10,42
Social Phobia

Phobias are one of the most common of the anxiety disorders. They are often accompanied by a strong fear of situations or objects. Specific phobia is characterized by a strong fear or anxiety that is out of proportion to the actual danger posed by the trigger. Social phobia involves a fear of social situations, which can lead to avoidance of social events. Both phobias can cause significant distress and impairment in daily life.

Substance Use Disorders

The DSM-IV-TR uses the term substance use disorders to describe patterns of substance use and substance dependence. Substance abuse refers to the use of substances that cause problems in an individual’s life. Substance dependence refers to the state of addiction, where the person has a strong urge to use the substance regularly. Treatment for substance use disorders typically involves a combination of medications, behavioral therapy, and support groups.

Etiology and Pathophysiology

Although substance abuse is not a new problem—people have been using drugs and alcohol for thousands of years—our understanding of abuse and addiction as diseases is more recent. Current and ongoing research has pointed to a complex, multifactorial etiology, which includes psychosocial, neurophysiological, developmental, and environmental components that lead to addiction. Self-medication of symptoms associated with psychiatric disorders provides another reason that a person may initiate drug abuse. Substance abuse disorders are more common among people with mood and anxiety disorders, and schizophrenia, all populations with altered levels of the neurotransmitter dopamine. Epidemiologic data indicate that there is a high comorbidity between drug dependence and depression. Approximately 40% of those with alcohol abuse or dependence also meet the criteria for major depressive disorder, and people who abuse substances are 20 times more likely to commit suicide than the general population. Research has also indicated that there is a high comorbidity between cannabis use and posttraumatic stress and depression.

Habitual use of drugs, including alcohol, is thought to induce adaptations in brain systems that alter the normal dopamine pathways and increase dopamine transmission. A neural pathway called the mesolimbic dopamine system is thought to gate signals that regulate biologic drives and motivation. These neurons send their axons to the nucleus accumbens, the striatum of the basal ganglia, and the frontal cortex. Drugs that facilitate dopamine transmission enhance the processes whereby otherwise neutral stimuli acquire incentive and reinforcing properties and facilitate drug-seeking behavior. Some drugs, such as cocaine and amphetamines, raise the level of dopamine in the nucleus accumbens by blocking the dopamine transporter, thereby prolonging the time that dopamine remains in the synaptic cleft. Although many drugs of abuse alter dopamine levels, not all of them act by way of the dopamine transporter. Nicotine, perhaps the most addictive of all drugs, enhances the release of dopamine by acting on presynaptic cholinergic receptors.

The rewarding effect of drug abuse results not only from the release of dopamine. As addiction develops, behavior also is influenced by a glutamatergic pathway. Glutamine is the major excitatory transmitter in the brain and spinal cord. Animal studies focusing on stimuli for relapse have found that exposure to a cue associated with substance use (i.e., stress or a single dose of the substance) results in activation of glutamatergic projections from areas of the brain that stimulate dopamine release from the nucleus accumbens. In addition,
there is a reported increase in GABA (a neurotransmitter that activates inhibitory receptors) levels during alcohol intoxication and opiate use. Opioid agonists appear to be rewarding because they inhibit GABA-ergic neurons that normally suppress dopaminergic neurons.

**Treatment**

Treatment of addiction requires an understanding of physiologic alterations in brain function that can cause relapse, even years after abstinence. Precipitants for relapse include stress, environmental cues, and exposure to the substance. Relapses are not uncommon and should not be considered as failures in treatment, but rather as a reflection of the nature of the illness. Because there is a high comorbidity between depression and drug dependence, professional treatment of preexisting psychiatric problems often decreases the use of illicit substances and helps prevent relapse. Treatments are varied and include biologic, behavioral, and psychosocial interventions. Biologic interventions are used in the maintenance of recovery from alcohol and opiates, such as heroin. Methadone, used in opiate addictions, has the narcotic properties of addiction and sedation, but lacks the euphoric effects of heroin and other opiates. Buprenorphine is a recently approved analgesic for treatment of opioid addictions with less euphoric and sedative properties than methadone. Naltrexone is used in treatment of alcohol and opiate addictions and works by blocking the opioid receptors and euphoric effects. It does not, however, eliminate cravings. These medications work best in conjunction with other therapies, such as self-help groups (Alcoholics Anonymous), individual therapy, family therapy, behavioral contracting, and social skills training.

**IN SUMMARY**

The development of a psychiatric disorder depends on a multitude of factors that include cumulative and developmental trauma and peritraumatic circumstances such as social supports, attachment, and the person’s neurobiologic and psychological profile. These factors create changes in the brain and in neural functioning. Recent research has deepened our understanding of how this complex interplay contributes to psychopathology and thus to how an individual can fortify against the ravages of trauma. Through identifying those who are vulnerable and at risk for developing psychopathology, clinicians can begin to frame interventions that bolster resilience and maintain psychological well-being. Resilience is the ability to successfully adapt to extreme stressors. Psychobiological resilience factors that have been identified include positive emotions or optimism and humor, an active coping style, cognitive flexibility, a moral compass, physical exercise, and social support. Undoubtedly the growing body of knowledge of the pathophysiology of psychiatric disorders will continue to lead to psychotherapies and lifestyle behaviors for enhancing resilience and the prevention of psychiatric disorders.

**DISORDERS OF MEMORY AND COGNITION**

After completing this section of the chapter, you should be able to meet the following objectives:

- Compare the causes associated with Alzheimer disease, vascular dementia, frontotemporal dementia, Creutzfeldt-Jakob disease, Wernicke-Korsakoff syndrome, and Huntington disease.
- Describe the changes in brain tissue that occur with Alzheimer disease.

Cognition refers to all the processes by which the sensory input is transformed, reduced, elaborated, stored, recovered, and used. It involves the perception of sensory input and the ability to learn and manipulate new information, recognize familiar objects and recollect past experiences, solve problems, think abstractly, and make judgments. Dementia is a syndrome of deterioration in cognitive function severe enough to interfere with occupational or social performance. It is a common and disabling disorder in older adults and is becoming a growing public health problem because of the numbers of older adults that experience cognitive loss.

**Normal Cognitive Aging**

Memory shows a slow, progressive impairment over the life span, and it is important to differentiate what can be termed “normal cognitive aging” from disorders of memory and cognition. Many older adults, of course, remain intellectually intact and make outstanding contributions later in life.

Short-term memory typically is well preserved during normal cognitive aging unless there is a high demand placed on processing resources. However, older adults may have greater difficulty than younger people in manipulating the information that is held in short-term memory. With regard to long-term memory, age-related impairments in free recall of stories and word lists are evident by 50 years of age. However, when structure is provided by the use of recognition cues, the age differences diminish, which suggests greater impairment of retrieval processes than of encoding and retrieval.

Memory problems associated with normal aging tend to reflect a generalized decrease in the efficiency with which information is processed and retrieved. Memory of a past event can be based on retrieval that is accompanied by recollection of specific details or on the feeling that the event is old or new, based on its familiarity. There is evidence that recollection is more dependent on the hippocampus and familiarity is more dependent on the entorhinal cortex, which relays information to and from the hippocampus. Healthy aging has greater effects on recollection than familiarity. Consciousness is a result of much more than one or two areas of the brain, but a huge neural network.
Evidence suggests that knowledge is first acquired through processing in one of the three polymodal association cortices (the prefrontal, limbic, and parietal–occipital–temporal cortices) that synthesize visual, auditory, and somatic sensory information. From there the information is conveyed to a series of parahippocampal and perirhinal cortices; then to the entorhinal cortex, dentate gyrus, hippocampus, and subiculum; and finally back to the entorhinal cortex. From the entorhinal cortex, the information is sent back to the parahippocampal cortices and finally back to the polymodal association areas of the neocortex. Thus, in processing information for explicit memory storage, the entorhinal cortex has dual functions. It is the main input to the hippocampus, and it is the major output to the hippocampus. With aging, there appears to be a reduced connectivity in the network that connects the hippocampus and association cortices but increased connectivity in the network that connects the entorhinal and association cortices. This suggests that older adults may compensate for hippocampal deficits by relying more on the entorhinal cortex.

Originally, it was believed that the laying down and retrieval of memories was due primarily to action of a single neurotransmitter, acetylcholine. This led to the development of acetylcholinesterase inhibitors to treat cognitive impairment. The further recognition of the role of the glutamate N-methyl-D-aspartate receptor led to the development of the drug, memantine. More recently, it was recognized that several neuropeptides (i.e., neuropeptide Y, orexin A, and the endogenous opioid peptides) also play an important role in memory. Although these peptides have the potential for enhancing memory at low levels, they can inhibit memory at high levels. There is also emerging evidence that several gastrointestinal hormones may contribute to memory, as evidenced by the observation that tasks learned before a meal is ingested are recalled better at a later time. This is thought to be related to the release of the gastrointestinal hormone cholecystokinin, which, through its stimulation of sensory afferent nerve fibers in the duodenum, signals the vagus nerve, eventually leading to activation of neurons in the hippocampus. An orexigenic peptide, ghrelin, which is produced in the fundus of the stomach, has receptors in the hippocampus and is also thought to enhance memory.

Dementia
Dementia or nonnormative cognitive decline can be caused by any disorder that permanently damages large association areas of the cerebral hemispheres or subcortical areas subserving memory and learning. The National Institute of Neurological Disorders and Stroke defines dementia as “[A] word for a group of symptoms caused by disorders that affect the brain. It is not a specific disease. People with dementia may not be able to think well enough to do normal activities, such as getting dressed or eating. They may lose their ability to solve problems or control their emotions. Their personalities may change. They may become agitated or see things that are not there.” Based on criteria in the third and fourth editions of the DSM (DSM-III and DSM-IV), the essential feature of dementia is impairment of short- and long-term memory, which is associated with deficits in abstract thinking, impaired judgment and other higher cortical functions, or personality change. The disturbance should be sufficiently severe as to interfere significantly with work or social activities. Common causes of dementia are Alzheimer disease, vascular dementia, frontotemporal dementia (FTD), Creutzfeldt-Jakob disease (CJD), Wernicke-Korsakoff syndrome, Huntington chorea, Parkinson disease (PD), and dementia with Lewy bodies. Ten percent of all people over 65 years of age and up to 50% of those over 85 years of age have dementia.

The diagnosis of dementia is based on assessment of the presenting problem; history about the person that is provided by an informant; complete physical and neurologic examination; evaluation of cognitive, behavioral, and functional status; and laboratory and imaging studies. The American Academy of Neurology practice parameters recommend structural neuroimaging, which may include CT or MRI, and screening for depression, vitamin B12 deficiency, and hypothyroidism. Depression is the most common treatable illness that may masquerade as dementia, and it must be excluded when a diagnosis of dementia is considered. This is important because cognitive functioning usually returns to baseline levels after depression is treated. Screening evaluations for subdural hematoma, cerebral infarcts, cerebral tumors, and normal-pressure hydrocephalus are also recommended. These and other reversible forms of dementia that should be ruled out can be remembered by the mnemonic DEMENTIA: drugs (drugs with anticholinergic activity), emotional (depression), metabolic (hypothyroidism), eyes and ears (declining vision and hearing), normal-pressure hydrocephalus, tumor or other space-occupying lesions, infection (human immunodeficiency virus infection or syphilis), and anemia (vitamin B12 or folate deficiency).

Alzheimer Disease
Dementia of the Alzheimer type occurs in middle or late life and accounts for 60% to 80% of all cases of dementia. The disorder affects more than 5.4 million Americans and may be the fourth leading cause of death in the United States. The risk for development of Alzheimer disease increases with age, and it is estimated that almost 50% of people 85 years of age and older live with this illness, with two thirds being women. It is projected that, unless a cure or prevention is developed, there will be 16 million Americans with Alzheimer disease by the year 2050.

Pathophysiology. The pathophysiologic aspects of Alzheimer disease involve neuropathologic and neurotransmitter changes. Alzheimer disease is characterized by cortical atrophy and loss of neurons, particularly in the parietal and temporal lobes (Fig. 22.3). With significant atrophy, there is ventricular enlargement (i.e., hydrocephalus) from the loss of brain tissue. The major microscopic features of Alzheimer disease are the presence of neuritic (senile) plaques, neurofibrillary tangles, and amyloid angiopathy. The neuritic plaques are
patches or flat areas composed of clusters of degenerating nerve terminals arranged around a central amyloid core\textsuperscript{100} (Fig. 22.4). The dominant component of the amyloid core is amyloid beta (A\textbeta{}), a peptide derived from the proteolysis of a larger membrane-spanning amyloid precursor protein (APP). There is increasing evidence that A\textbeta{} is the critical molecule in the pathogenesis of Alzheimer disease. Full-length APP has an intracellular region, a membrane-spanning sequence, and an extracellular region. The normal degradation of APP involves cleavage in the middle of the A\textbeta{} domain by a proteolytic \textalpha{}-secretase enzyme, with the release of two soluble nonamyloidogenic pieces. However, APP can also be cleaved at either end of the A\textbeta{} domain, leading to the release of intact and highly amyloidogenic A\textbeta{} that accumulates in senile plaques as amyloid fibrils. There are at least three distinct forms of secretase enzymes (\textalpha{}, \textbeta{}, \textgamma{}-secretase). Evidence suggests that cleavage by the \textbeta{}- and \textgamma{}-secretase leads to the generation of A\textbeta{}.\textsuperscript{100}

The neurofibrillary tangles, found in the cytoplasm of abnormal neurons, consist of fibrous proteins that are wound around each other in a helical fashion (Fig. 22.5). These tangles are resistant to chemical or enzymatic breakdown, and they persist in brain tissue long after the neuron in which they arose has died and disappeared. A major component of the paired helical filaments is an abnormally hyperphosphorylated form of the protein tau, an axonal microtubule-associated protein that enhances microtubule assembly.\textsuperscript{99,100}

Some plaques and tangles can be found in the brains of older people who do not show cognitive impairment. The number and distribution of the plaques and tangles appear to contribute to the intellectual deterioration that occurs with Alzheimer disease. In people with Alzheimer disease, the plaques and tangles and associated neuronal loss and glial reaction are evident earliest in the entorhinal cortex, then spread through the hippocampal formation and isocortex, and then extend to the neocortex.\textsuperscript{100} Neurochemically, Alzheimer disease has been associated with a decrease in the level of choline acetyltransferase activity in the cortex and hippocampus. This enzyme is required for the synthesis of acetylcholine, a neurotransmitter that is associated with memory. The reduction in choline acetyltransferase is quantitatively related to the numbers of neuritic plaques and severity of dementia.
It is likely that Alzheimer disease is caused by several factors that interact differently. Progress on the genetics of inherited early-onset Alzheimer disease shows mutations in at least three genes—the amyloid precursor protein (APP) gene on chromosome 21; presenilin-1 (PS1), a gene on chromosome 14; and presenilin-2 (PS2), a gene on chromosome 1—can cause Alzheimer disease in certain families.\(^6^4\) The \(APP\) gene is associated with an autosomal dominant form of early-onset Alzheimer disease and can be tested clinically. Persons with Down syndrome (trisomy 21) develop the pathologic changes of Alzheimer disease and can be tested clinically. Persons with Down syndrome exhibit the pathologic features of Alzheimer disease as they age. PS1 and PS2, both intracellular proteins, are components of \(\gamma\)-secretase and possibly part of a multiprotein complex containing the proteolytic site for breakdown of A\(\beta\). A fourth gene, an allele (\(\alpha\)-4) of the apolipoprotein E (ApoE) gene found on chromosome 19, increases the risk of Alzheimer disease and lowers the age of onset. ApoE can bind A\(\beta\) and is present in plaques, but how this allele increases the risk of Alzheimer disease has not been established.\(^9^9\)

Although age is the greatest risk, additional factors have been identified as adding to the risks for development of Alzheimer disease. These include head trauma, inflammatory factors, and oxidative stress. Studies have looked at exercise as a possible protective factor in maintaining hippocampal health and increasing hippocampus size.\(^1^0^1\)

**Clinical Manifestations.** Alzheimer-type dementia follows an insidious and progressive course, with an average survival of 8 to 10 years after diagnosis.\(^9^7\) The hallmark symptoms are loss of short-term memory and denial of such memory loss, difficulty with language, and changes in behavior.\(^9^9\) Various stages of the disease have been recognized, ranging from four to the more nuanced seven stages identified by the Alzheimer Association.\(^1^0^2\) All are characterized by progressive degenerative changes.\(^1^0^3\) The initial change is subtle, characterized by short-term memory loss that often is difficult to differentiate from the normal forgetfulness that occurs in older adults, and usually is reported by caregivers and denied by the person. Although most older adults have trouble retrieving from memory incidental information and proper names, people with Alzheimer disease randomly forget important and unimportant details. They forget where things are placed, get lost easily, and have trouble remembering appointments and performing novel tasks. Mild changes in personality, such as lack of spontaneity, social withdrawal, and loss of a previous sense of humor, occur during this stage.

As the disease progresses, the person with Alzheimer disease enters the moderate stage. This stage may last several years and is marked by a more global impairment of cognitive functioning. During this stage, there are changes in higher cortical functioning needed for language, spatial relationships, and problem solving. Depression may occur in people who are aware of their deficits. There is extreme confusion, disorientation, lack of insight, and inability to carry out the activities of daily living. Personal hygiene is neglected, and language becomes impaired because of difficulty in remembering and retrieving words. Behavioral changes can include agitation, sleep problems, restlessness and wandering, aggression, and suspiciousness. Some people may become hostile and abusive toward family members. People who enter this stage become unable to live alone and should be assisted in making decisions about supervised placement with family members or friends or in a community-based facility.

Severe Alzheimer disease is the last stage of the disease. It is characterized by a loss of ability to respond to the environment. People in this stage require total care and spend most of their time bedridden. Death can occur as a result of complications related to chronic debilitation.

**Diagnosis and Treatment.** Alzheimer disease is essentially a diagnosis of exclusion. There are no peripheral biochemical markers or tests for the disease. The diagnosis can be confirmed only by microscopic examination of tissue obtained from a cerebral biopsy or at autopsy. The diagnosis is based on clinical findings. It is very difficult to predict if a person with mild cognitive impairment will progress to Alzheimer disease.

The diagnostic procedures for Alzheimer disease involve numerous steps, and a Differential Diagnosis in Alzheimer Algorithm has been developed.\(^1^0^3\) A diagnosis of Alzheimer disease requires the presence of dementia established by clinical examination and documented by results of a Mini-Mental State Examination, Blessed Dementia Test, or similar mental status test; no disturbance in consciousness; onset between 40 and 90 years of age, most often after 65 years of age; and absence of systemic or brain disorders that could account for the memory or cognitive deficits. Brain imaging, CT scan, or MRI is done to exclude other brain disease. Metabolic screening should be done for known reversible causes of dementia such as vitamin B\(_{12}\) deficiency, thyroid dysfunction, and electrolyte imbalance.

There is no curative treatment for Alzheimer dementia. Drugs are used primarily to slow the progression and to control depression, agitation, or sleep disorders. Two major goals of care are maintaining the person’s socialization and providing support for the family. Self-help groups that provide support for family and friends have become available, with support from the Alzheimer Disease and Related Disorders Association. Day care and respite centers are available in many areas to provide relief for caregivers and appropriate stimulation for the patient.

Although there is no current drug therapy that is curative for Alzheimer disease, some show promise in terms of slowing the progress of the disease. Cholinesterase inhibitors have been shown to be effective in slowing the progression of the disease by potentiating the action of available acetylcholine.\(^1^0^4,1^0^5\) These drugs—donepezil, rivastigmine, and galantamine—inhibit acetylcholinesterase, preventing the metabolism of endogenous acetylcholine, and are used in the early stages of the disease for mild cognitive impairment. Thus far, such
therapy has not halted disease progression, but it can slow the disease progression by approximately 6 to 12 months. The therapeutic effects cease when the medication is discontinued.

Memantine, an N-methyl-d-aspartate antagonist, has been effective for many in treating moderate to severe Alzheimer disease. This medication may act by interfering with the glutamatergic excitotoxicity caused by the ischemia and amyloid deposits associated with the disease, or it may provide symptomatic improvement through effects on the function of hippocampal neurons. This medication, like the cholinesterase inhibitors, does not reverse the disease, but does provide a modest delay in functional loss.

Although no drugs that cure Alzheimer disease have been identified, there are multiple research studies looking at nonpharmacological variables that may or may not influence a person to develop dementia of Alzheimer disease or some other type of dementia. For example, one study researched if people who had metabolic syndrome were at greater risk for developing dementia and found that older adults diagnosed with metabolic syndrome when they were in old age was not a predictor of dementia. However, people who had advanced oral carcinoma were at greater risk for developing decreased cognitive function, and the amount of lost cognitive function was correlated with the tumor size. Another study showed that people with severe brain injuries were not at higher risk for developing dementia in later life. Another study showed that people who had slow gait speed when walking were at higher risk for adverse outcomes and this was highly correlated with the diagnosis of being “frail” or having the frailty syndrome, which includes having some type of dementia. One might expect that the consistency of health care provider and case manager would be significant in obtaining an earlier diagnosis and having some treatment started earlier. However, one study demonstrated that using case management with people with early symptoms of dementia and their caregiver(s) did not make a difference in the person’s overall care and progression to more extensive dementia. On the other end of the continuum, dementia was found to be highly correlated with people suffering a hip fracture and experiencing increased postoperative morbidity and mortality.

Psychotropic medications, such as antipsychotics and mood stabilizers, may be used to assist in the behavioral management of the disease. Interventions also include environmental adjustments, behavioral intervention, and education and support for caregivers. Caregiver support is essential because they are responsible for supervising people who live in the community and continue to visit and provide support after the person has been institutionalized. They are also responsible for administering medications, implementing nonpharmacologic treatments, and promoting the person’s general health and well-being.

Vascular Dementia

Vascular dementia is caused by brain injury resulting from ischemic or hemorrhagic damage. Approximately 1% to 4% of dementias are vascular in origin, with increasing age being the most significant risk variable in terms of experiencing a cerebrovascular event. The incidence is closely associated with hypertension, but also with arrhythmias, myocardial infarction, peripheral vascular disease, lipid abnormalities, diabetes mellitus, autoimmune and infectious vasculitis, and smoking.

Vascular dementia differs from Alzheimer disease in its presentation and tissue abnormalities. Slowness in psychomotor functioning is a main clinical feature of this dementia, and symptoms of depression are often present. The onset may be gradual or abrupt, the course usually is a stepwise progression, and there are focal neurologic symptoms related to local areas of infarction.

Frontotemporal Dementia

FTD refers to a group of rare disorders that cause atrophy of the frontal and anterior temporal lobes of the brain. Originally known as Pick disease, FTD now refers to a syndrome that includes primary progressive aphasia, corticobasal degeneration, progressive supranuclear palsy, and semantic dementias. The disease occurs with the same frequency in men and women, with onset between 35 and 75 years of age.

There are two distinct clinical presentations that reflect the symptoms of FTD: behavior and language. The former is more common, with behavioral presentations of disinhibited and impulsive actions or apathy, with inappropriate social behavior. The behavioral abnormalities can be quite extreme and can be misdiagnosed as schizophrenia or psychotic depression. The second type of FTD involves disturbances in understanding or expressing language. There is no prominent memory loss, such as with Alzheimer disease.

Diagnosis is based on evidence of cognitive impairment and exclusion of other illnesses that cause cognitive and behavioral deficits. Neuroimaging can be helpful in distinguishing FTD from other types of cognitive disorders. Typically, structural imaging shows anterior temporal and frontal lobe atrophy. The course of the disease is relentless, with death ensuing within 2 to 10 years. The immediate cause of death usually is infection.

Creutzfeldt-Jakob Disease

CJD is one of three prion diseases (spongiform encephalopathies). CJD is extremely rare disorder, affecting only one person per million each year worldwide. In the United States, there are approximately 200 cases per year. CJD causes severe degenerative dementia. There are four categories of CJD: sporadic, hereditary, acquired, and new variant CJD. Sporadic, in which the disease occurs without known risk factors, is the most common form, accounting for up to 85% of the cases. Familial or hereditary CJD represents 10% to 15% of cases, and acquired CJD is rare, representing less than 1% of cases. The new variant CJD is similar to sporadic CJD except there are severe behavioral and sensory disturbances, and it occurs in much younger people (in their 20s). Variants of the disease occur in animals, including scrapie in sheep and goats and bovine spongiform encephalopathy (BSE; mad cow disease) in cattle.
CJD causes degeneration of the pyramidal and extrapyramidal systems and is distinguished most readily by its rapid course. Affected people usually are demented within 6 months of onset. The disease is uniformly fatal, with death often occurring within months, although a few people may survive for several years. The early symptoms consist of abnormalities in personality and visual–spatial coordination and impaired memory and judgment. Extreme dementia, insomnia, blindness, and ataxia follow as the disease progresses.

Wernicke-Korsakoff Syndrome

Wernicke-Korsakoff syndrome most commonly results from chronic alcoholism. Figure 22.6 illustrates the areas of the brain impacted by chronic ethanol abuse. Wernicke disease is characterized by acute weakness and paralysis of the extraocular muscles, nystagmus, ataxia, and confusion. The affected person also may have signs of peripheral neuropathy. There may be signs attributable to alcohol withdrawal such as delirium, confusion, and hallucinations. This disorder is caused by a deficiency of thiamine (vitamin B1), which directly interferes with production of glucose, the brain’s main nutrient.

The Korsakoff component of the syndrome involves the chronic phase with severe impairment of recent memory. There often is difficulty in dealing with abstractions, and the person’s capacity to learn is defective. Confabulation (i.e., recitation of imaginary experiences to fill in gaps in memory) probably is the most distinctive feature of the disease. Polyneuritis also is common. Unlike Wernicke disease, Korsakoff psychosis does not improve significantly with treatment.

Huntington Disease

Huntington disease (HD) is a hereditary disorder characterized by chronic progressive chorea, psychological changes, and dementia. Although the disease is inherited as an autosomal dominant disorder, the age of onset most commonly is in the fourth and fifth decades. By the time the disease has been diagnosed, the person often has passed the gene on to his or her children. Approximately 10% of HD cases involve juvenile onset. Juveniles affected rarely live to adulthood.

HD produces localized death of brain cells. The first and most severely affected neurons are of the caudate nucleus and putamen of the basal ganglia. The neurochemical changes that occur with the disease are complex (Fig. 22.7). The neurotransmitter GABA is an inhibitory neurotransmitter in the basal ganglia. Postmortem studies have shown a decrease of GABA and GABA receptors in the basal ganglia of people with HD. Likewise, the levels of acetylcholine, an excitatory neurotransmitter in the basal ganglia, are reduced in people with HD. The dopaminergic pathway of the nigrostriatal system, which is affected in PD, is preserved in HD, suggesting that an imbalance in dopamine and acetylcholine may contribute to manifestations of the disease.

Depression and personality changes are the most common early psychological manifestations; memory loss often is accompanied by impulsive behavior, moodiness, antisocial behavior, and a tendency toward emotional outbursts. An estimated 30% of people with HD experience these manifestations. Other early signs of the disease are lack of initiative, loss of spontaneity, and inability to concentrate. Fidgeting or restlessness may represent early signs of dyskinesia, followed by choreiform and some dystonic posturing. Eventually, progressive rigidity and akinesia (rather than chorea) develop in association with dementia. Symptoms of juvenile-onset HD include Parkinson-like dystonias and seizures.
There is no cure for HD. The treatment is largely symptomatic. Drugs may be used to treat the dyskinesias and behavioral disturbances. The HD gene is on chromosome 4. The discovery of a marker probe for the gene locus has enabled testing that can predict whether a person will develop the disease.

**Dementia with Parkinson Disease**

Approximately 20% of people with PD develop dementia. Of those who develop dementia, it is usually after 70 years of age and after they have developed the classic symptoms of PD such as bradykinesia, tremor, rigidity, and postural instability. There is much controversy over whether people with dementia who have PD also may have dementia with Lewy bodies or whether the dementia is a result of the PD or something else. On autopsy some brains of people with PD and Alzheimer contain Lewy bodies.

**Dementia with Lewy Bodies**

Dementia with Lewy bodies is becoming a more common type of progressive dementia. The defining characteristics of this disease are fluctuations in alertness and attention, recurrent visual hallucinations, and parkinsonian motor symptoms. It is controversial as to whether this disease is a separate disorder or if it is part of PD and AD. This dementia is due to a buildup of Lewy bodies, which are alpha-synuclein proteins that accumulate in the nuclei of neurons controlling memory and motor control. People with dementia of Lewy bodies experience an increase in dementia if they receive anticholinergic drugs and they also should avoid antipsychotics. These people do best on cholinesterase inhibitors.

**IN SUMMARY**

Cognition refers to all the processes by which sensory input is transformed, reduced, elaborated, stored, recovered, and used. It is important to differentiate what can be termed “normal cognitive aging” from disorders of memory and cognition. Memory problems that are associated with normal aging tend to reflect a generalized decrease in the efficiency with which information is processed and retrieved. Memory of a past event can be based on retrieval that is accompanied by recollection of specific details or on the feeling that the event is old or new based on its familiarity. There is evidence that recollection is more dependent on memory impairment and terminates in an inability to recognize family or friends and the loss of control over bodily functions. Ischemic or hemorrhagic damage is associated with vascular dementia and FTD with atrophy of the frontal and temporal lobes. CJD is a rare, rapidly progressive form of dementia. Wernicke-Korsakoff syndrome most often results from chronic alcoholism. HD is a hereditary disorder characterized by chronic and progressive chorea, psychological changes, and dementia. There is controversy as to whether dementia with Lewy bodies is connected to Alzheimer and PD. Currently dementia with Lewy bodies is categorized as an alpha-synucleinopathy.

**REVIEW EXERCISES**

1. A 45-year-old woman was brought to the emergency department after being picked up by the police. She was wandering in and out of traffic saying someone was after her and was recognized as a homeless person. Her appearance is dirty and disheveled, and she is wearing several layers of clothing, although it is summer. She smacks her lips and at times does not seem to understand questions. Periodically she laughs for no apparent reason and often repeats the words of her questioner. She has a 20-year history of schizophrenia with multiple admissions. A. List the positive and negative signs she exhibits. B. What are the brain areas and transmitters responsible for these signs? C. What are the DSM-IV-TR criteria that would have led to her diagnosis?
2. A 35-year-old woman was recently admitted with suicidal tendencies shortly after a diagnosis of major depression. She had lost 40 lb in the last 6 months. She appears tired and supplies only short answers to questions. She complains of dizziness and informs the nurse that it is not her business to discuss her suicidal thoughts. Her husband says she relies heavily on alcohol.

A. Describe some of her manifestations. Why is she using alcohol?
B. Provide an explanation for her tiredness.
C. What areas of the brain and neurotransmitters are involved in depression? How is it different from mania?
D. What are the possible roles of thyroid and adrenal hormones?

3. A 40-year-old woman is seen in the emergency department in a state of severe panic. She has had panic attacks for several months and had not sought treatment until her husband came home and found her sitting in the bedroom unable to move. She had been there all day and had soiled her clothing. In the emergency department, she appeared frightened and paced in one area. She had difficulty understanding questions and cooperated only as long as she could pace. The husband relates that his wife had been under a lot of stress in her job and had recently lost some important clients.

A. What are some manifestations of her panic?
B. What is the biologic cause of anxiety disorders (include the brain structures and neurotransmitters involved)?
C. Describe the physiologic manifestations of a panic attack.

Visit thePoint http://thePoint.lww.com for animations, journal articles, and more!
Mr. Pall, a 20 year old college student, presents to his primary care provider complaining of a 2-day history of “almost painless” left red eye. He attended a friend’s gig at a local club 48 hours ago. He stayed out late at the club, which was full of cigarette smoke. However, he states that smoke has never bothered his eyes before.

He denies any trauma to his eye, but reports a head cold of several days duration. He has a history of 5 years of contact lens use (daily wear). His medical history is positive for presbyopia, allergic rhinoconjunctivitis, fracture of the right wrist at age 9 from skateboarding, and an appendectomy last summer. He says that he may have fallen asleep without removing his contacts, which happens about twice a month. He denies blurry vision, any change in vision since the redness began, or pain in eyeball with or without eye movement. He reports that his “left eye is glued shut” upon waking. Upon examination, the primary care provider notes an extremely red, injected, and swollen left conjunctiva with slight yellow drainage. Right eye shows similar findings, but to a lesser extent.

Vision is within normal limits (WNL) and no foreign bodies are noted upon fluorescein stain. The primary care provider diagnoses Mr. Pall with left and right bacterial conjunctivitis and prescribes antibiotic drops. Mr. Pall is taught how to administer the drops as well as hygienic practices to prevent reinfection.

You will find out more about bacterial conjunctivitis in Chapter 23.

The World Health Organization (WHO) reports 314 million people worldwide are visually impaired with as many as 45 million of those being blind. Of these people, 80% are believed to have avoidable blindness and visual impairment. In 2008, the World Health Assembly stated that a staggering proportion of visual illness, 90%, is concentrated in low- and middle-income countries. As a result, the sixty-first World Health Assembly passed a 2009–2013 Action Plan for the Prevention of Avoidable Blindness and Visual Impairment, which presents strategies to address preventable illness.

Alterations in vision can result from disorders of the eyelids and optic globe (conjunctiva, cornea, and uvea), intraocular pressure (glaucoma), lens (cataract), vitreous humor and retina (retinopathy and macular degeneration), optic pathways and visual cortex, and extraocular muscles and eye movement.
The optic globe, commonly called the eyeball, is a remarkably mobile, nearly spherical structure contained in a pyramid-shaped cavity of the skull called the orbit. The eyeball occupies only the anterior one fifth of the orbit. The remainder is filled with muscles, nerves, the lacrimal gland, and adipose tissue that support the normal position of the optic globe. Exposed surfaces of the eyes are protected by the eyelids, which are mucous membrane–lined skin flaps that provide a means for shutting out most light. Tears bathe the anterior surface of the eye. They prevent friction between it and the lid, maintain hydration of the cornea, and protect the eye from infection and irritation by foreign objects. Figure 23.1 illustrates the eyelid and lacrimal apparatus.

Three distinct layers form the wall of the eyeball—the sclera or outer supporting layer, the uvea or middle vascular layer, and the retina, which is composed of the neuronal retinal layer and the outer pigmented layer (see Fig. 23.2). The outer layer of the eyeball consists of a tough, opaque, white, fibrous layer called the sclera. It is strong yet elastic and maintains the shape of the globe. The sclera is continuous with the cornea anteriorly and with the cranial dural sheath that surrounds and protects the optic nerve posteriorly. The choroid (uvea) predominantly provides vascular support of the retina, whereas the retina is the neurosensory tissue that provides the sensory input for sight.

**Key Points**

**Vision**

- Vision is a special sensory function that incorporates the visual receptor functions of the eyeball, the optic nerve, and optic pathways that carry and distribute sensory information from the optic globe to the central nervous system (CNS) via photoreceptors in the retina, and the primary and visual association cortices that translate the sensory signals into visual images.

- Binocular vision depends on the coordination of three pairs of extraocular nerves that provide for the conjugate eye movements, with optical axes of the two eyes maintained parallel with one another as the eyes rotate in their sockets.

**Disorders of the Eyelids**

The upper and lower eyelids, the palpebrae, are modified folds of skin with associated muscle and cartilaginous plates that protect the eyeball. The palpebral fissure is the oval opening between the upper and lower eyelids. At the corners of the eye, where the upper and lower lids meet, is an angle called the canthus. The lateral canthus is the outer, or temporal, angle, and the medial canthus is the inner, or nasal, angle. In each lid, a tarsus, or plate of dense connective tissue, gives the lid its shape (Fig. 23.3). Each tarsus contains modified sebaceous glands, called meibomian glands, the ducts of which open onto the eyelid margins. Sebaceous secretions of the meibomian glands enable airtight closure of the lids and prevent rapid evaporation of tears.

Two striated muscles, the levator palpebrae superioris and the orbicularis oculi, provide for movement of the eyelids. The levator palpebrae superioris, innervated by the oculomotor nerve (cranial nerve [CN] III), serves to raise the upper lid. Encircling the eye is the orbicularis oculi muscle, which is supplied by the facial nerve (CN VII). When this muscle contracts, it closes the eyelids. Between the nose and medial angle of the eye is the medial palpebral ligament, which connects to the medial margin of the orbit (see Fig. 23.3). A similar palpebral ligament attaches to the lateral margin of the orbit. The orbicularis oculi nerve inserts into the medial palpebral ligament that passes through each eyelid and inserts.
into the lateral palpebral junction. The four recti and two oblique muscles provide for movement of the eyeball.

**Eyelid Weakness**

Drooping of the eyelid is called *ptosis*. Figure 23.4 illustrates ptosis with Horner syndrome. It can result from weakness of the levator muscle that elevates the upper lid in conjunction with the unopposed action of the orbicularis oculi that forcefully closes the eyelids. Weakness of the orbicularis oculi causes an open eyelid, but not ptosis. Neurologic causes of eyelid weakness include damage to the innervating cranial nerves or to the nerves’ central nuclei in the midbrain and the caudal pons.

Normally, the edges of the eyelids, or palpebrae, are in such a position that the palpebral conjunctiva that lines the eyelids is not exposed and the eyelashes do not rub against the cornea. Turning in of the lid margin is called *entropion*. It is usually caused by scarring of the palpebral conjunctiva or degeneration of the fascial attachments to the lower lid that occurs with aging. Corneal irritation may occur as the eyelashes turn inward. *Ectropion* refers to eversion of the lower lid margin. It is the most frequent lid condition and is usually bilateral and caused by relaxation of the orbicularis oculi muscle because of CN VII weakness or the aging process. Ectropion causes tearing and ocular irritation and may lead to inflammation of the cornea.
Entropion and ectropion can be treated surgically. Electrocautery penetration of the lid conjunctiva also can be used to treat mild forms of ectropion. After electrocautery, contraction of the resulting scar tissue usually draws the lid up to its normal position.

Eyelid Inflammation

Blepharitis is a common bilateral inflammation of the anterior or posterior structures of eyelid margins. Anterior blepharitis involves the eyelid skin, eyelashes, and associated glands (Fig. 23.5). Two main types of anterior blepharitis occur—inflammatory and infectious. The inflammatory form is usually associated with seborrhea (i.e., dandruff) of the scalp or brows. Infectious blepharitis may be caused by Staphylococcus epidermidis or Staphylococcus aureus, in which case the lesions are often ulcerative. The main symptoms of anterior blepharitis are irritation, burning, redness, and itching of the eyelid margins. Treatment includes careful cleaning with a damp applicator to remove the scales. When the disorder is associated with a microbial infection, an antibiotic (ointment or drops) is prescribed.

Posterior blepharitis is inflammation of the eyelids that involves the meibomian glands. It may result from a bacterial infection, particularly with staphylococci, or dysfunction of the meibomian glands, in which there is a strong association with acne rosacea. The meibomian glands and their orifices are inflamed, with dilation of the glands, plugging of the orifices, and abnormal secretions. The tears may be frothy and abnormally greasy from the meibomian secretions. Treatment of posterior blepharitis is determined by associated conjunctival and corneal changes. Initial therapies can include warm compression of the lids and use of flaxseed or fish oil tablets to provide omega-3 fatty acid benefits to meibomian oil secretions. Long-term, low-dose systemic antibiotic therapy guided by results of bacterial cultures along with short-term topical steroids may also be needed.

A hordeolum, or stye, is caused by infection of the sebaceous glands of the eyelid and can be internal or external. The main symptoms are pain, redness, and swelling. The treatment is similar to that for abscesses in other parts of the body. Heat such as a warm compress is applied, and short-term treatment with systemic antibiotics (e.g., doxycycline) may be used to reduce or eliminate the infection. Incision or expression of the infectious contents of the abscess may be necessary.

A chalazion is a chronic inflammatory granuloma of a meibomian gland that may follow an internal hordeolum. It is characterized by a small, nontender nodule on the upper or lower lid. The conjunctiva around the chalazion is red and elevated. If the chalazion is large enough, it may press on the eyeball and distort vision. Treatment consists of surgical excision or direct glucocorticoid injection.

Disorders of the Lacrimal System

The lacrimal system includes the major lacrimal gland, which produces the tears; the puncta, canaliculi, and tear sac, which collect the tears; and the nasolacrimal duct, which empties the tears into the nasal cavity. The lacrimal gland lies in the orbit, superior and lateral to the eyeball (see Fig. 23.1). Approximately 12 small ducts connect the lacrimal gland to the superior conjunctival fornix. Tears contain approximately 98% water, 1.5% sodium chloride, and small amounts of potassium, albumin, and glucose. The function of tears is to provide a smooth optical surface by abolishing minute surface irregularities. Tears also wet and protect the delicate surface of the cornea and conjunctiva. They flush and remove irritating substances and microorganisms and provide the cornea with necessary nutrient substances. Tears also contain lysozymes and immunoglobulin A (IgA), IgG, and IgE, which synergistically act to protect against infection. Although IgA predominates, IgE concentrations are increased in some allergic conditions.

Dry Eyes

The thin film of tears that covers the cornea is essential in preventing drying and damage of the outer layer of the cornea. This tear film is composed of three layers:

1. A superficial lipid layer, which is derived from the meibomian glands and thought to retard evaporation
2. An aqueous layer, secreted by the lacrimal glands
3. A mucinous layer, which overlies the cornea and epithelial cells
Because the epithelial cell membranes are hydrophobic and cannot be wetted by aqueous solutions alone, the mucinous layer plays an essential role in wetting these surfaces. Periodic blinking of the eyes is needed to maintain a continuous tear film over the ocular surface.

Several conditions reduce the functioning of the lacrimal glands. With aging, the lacrimal glands diminish their secretion, and as a result, some older adults awaken from a night’s sleep with highly irritated eyes. Dry eyes also can result from loss of reflex lacrimal gland secretion because of congenital defects, infection, irradiation, damage to the parasympathetic innervation of the gland, and medications such as antihistamines and drugs with an anticholinergic action. Wearing contact lenses can contribute to an interruption of the normal tear film. Sjögren syndrome is a systemic disorder in which lymphocytes and plasma cells infiltrate the lacrimal and parotid glands. The disorder is associated with diminished salivary and lacrimal secretions, resulting in keratoconjunctivitis sicca (i.e., dry eye syndrome) and xerostomia (i.e., dry mouth). The syndrome occurs mainly in women near menopause and is often associated with connective tissue disorders such as rheumatoid arthritis.

People with dry eyes complain of a dry or gritty sensation in the eye, burning and itching, inability to produce tears, photosensitivity, redness, pain, and difficulty in moving the eyelids. Some people experience excess tearing as the eyes attempt to react to dry symptoms. Dry eyes and the absence of tears can cause keratinization of the cornea and conjunctival epithelium. In severe cases, corneal ulcerations can occur.

The treatment of dry eyes includes frequent instillation of artificial tear solutions into the conjunctival sac. More prolonged duration of action can be obtained from topical preparations containing methylcellulose or polyvinyl alcohol. An ointment is useful for prolonged lubrication. Overall, these artificial tear preparations are safe and without side effects. However, the preservatives necessary to maintain their stability can be irritating to the cornea. Further treatment can include occlusion of the lacrimal puncta with silicone plugs or use of therapeutic topical drugs to increase natural tear volume. Increased intake of omega-3 fatty acids has also been shown to provide improvement in dry eye symptoms.

**Dacryocystitis**

Dacryocystitis is an infection of the lacrimal sac. It occurs most often in infants or in people older than 54 years of age. In fact, 75% of people diagnosed with dacryocystitis are postmenopausal women. It is usually unilateral and most often occurs secondary to obstruction of the nasolacrimal duct. Often the cause of the obstruction is unknown, although there may be a history of severe trauma to the midface. The symptoms include tearing and discharge, pain, swelling, and tenderness. The treatment includes application of warm compresses and antibiotic therapy. In chronic forms of the disorder, surgical repair of the tear duct may be necessary.

In infants, dacryocystitis is usually caused by failure of the nasolacrimal ducts to open spontaneously before birth. When a duct fails to open, a secondary dacryocystitis may develop. These infants are usually treated with gentle massage of the tear sac, instillation of antibiotic drops into the conjunctival sac, and, if that fails, probing of the tear duct.

**IN SUMMARY**

The eyelids serve to protect the eye. Ptosis refers to drooping of the upper lid, which is caused by injury to CN III. Entropion, which refers to turning in the upper eyelid and eyelashes, is discomforting and causes corneal irritation. Ectropion, or eversion of the lower eyelid, causes tearing and may lead to corneal inflammation. Marginal blepharitis is the most common disorder of the eyelids. It commonly is caused by a staphylococcal infection or seborrhea (i.e., dandruff).

The lacrimal system includes the major lacrimal gland, which produces the tears; the puncta and tear sac, which collect the tears; and the nasolacrimal duct, which empties the tears into the nasal cavity. Tears protect the cornea from drying and irritation. Impaired tear production or conditions that prevent blinking and the spread of tears produce drying of the eyes and predispose them to corneal irritation and injury. Dacryocystitis is an inflammation caused by an infection of the lacrimal sac.

**DISORDERS OF THE CONJUNCTIVA, CORNEA, AND UVEAL TRACT**

After completing this section of the chapter, you should be able to meet the following objectives:

- Compare symptoms associated with red eye caused by conjunctivitis, corneal irritation, and acute glaucoma.
- Characterize the manifestations, treatment, and possible complications of bacterial, *Acanthamoeba*, and herpes keratitis.
- Describe tests used in assessing the pupillary reflex and cite the possible causes of abnormal pupillary reflexes.

**Disorders of the Conjunctiva**

The conjunctiva is a delicate mucous membrane that lines the anterior surface of both eyelids as the *palpebral conjunctiva* and folds back over the anterior surface of the optic globe as the *ocular or bulbar conjunctiva*. The ocular conjunctiva covers only the sclera or white portion of the optic globe, not the cornea. When both eyes are closed, the conjunctiva lines the closed conjunctival sac. Although the conjunctiva protects the eye, its main function is the production of a lubricating mucus that bathes the eye and keeps it moist.

Conjunctivitis, or inflammation of the conjunctiva (i.e., red or pink eye), is one of the most common forms of eye disease. It may result from bacterial or viral infection, allergens, chemical agents, physical irritants, or radiant energy. Depending on the cause, conjunctivitis can vary in severity
from a mild hyperemia (redness) with tearing to severe conjunctivitis with purulent drainage. The conjunctiva is extremely sensitive to irritation and inflammation.

Clinical manifestations of conjunctivitis include a foreign body sensation, a scratching or burning sensation, itching, and photophobia. Severe pain suggests corneal rather than conjunctival disease. A discharge, or exudate, may be present. It is usually watery when the conjunctivitis is caused by allergy, a foreign body, or viral infection and mucopurulent in the presence of bacterial or fungal infection. A characteristic of many forms of conjunctivitis is papillary hypertrophy. This occurs because the palpebral conjunctiva is bound to the tarsus by fine fibrils. As a result, inflammation that develops between the fibrils causes the conjunctiva to be elevated in mounds called papillae. When the papillae are small, the conjunctiva has a smooth, velvety appearance. Red papillary conjunctivitis suggests bacterial or chlamydial conjunctivitis. In allergic conjunctivitis, the papillae often become flat-topped, polygonal, and milky in color and have a cobblestone appearance.

The diagnosis of conjunctivitis is based on history, physical examination, and microscopic and culture studies to identify the cause. Because a red eye may be the sign of several eye conditions, it is important to differentiate between redness caused by conjunctivitis and that caused by more serious eye disorders, such as corneal lesions and acute glaucoma. In contrast to corneal lesions and acute glaucoma, conjunctivitis produces infection (i.e., enlargement and redness) of the peripheral conjunctival blood vessels rather than those radiating around the corneal limbus. Conjunctivitis also produces only mild discomfort compared with the moderate to severe discomfort associated with corneal lesions or the severe and deep pain associated with acute glaucoma. Infectious forms of conjunctivitis are usually bilateral and may involve other family members and associates. Unilateral disease suggests sources of irritation such as foreign bodies or chemical irritation.

Remember Mr. Pall from the unit opener case study. His primary care provider diagnosed him with bacterial conjunctivitis based on the history and physical examination findings. He complains of his left eye being stuck together like glue due to the huge amounts of yellow drainage upon awakening, and Mr. Pall has no other concerns besides the conjunctivitis, except that he has an upper respiratory infection. On physical examination, injected and swollen conjunctiva, red eye, and large amounts of drainage were found. He has some slight discomfort but no pain.

**Allergic Conjunctivitis**

Allergic conjunctivitis encompasses a spectrum of conjunctival conditions usually characterized by itching. The most common of these is seasonal allergic rhinoconjunctivitis, or hay fever. Seasonal allergic conjunctivitis is an IgE-mediated hypersensitivity reaction precipitated by small airborne allergens such as pollens. It typically causes bilateral tearing, itching, and redness of the eyes (Fig. 23.6).

The treatment of seasonal allergic rhinoconjunctivitis includes allergen avoidance and the use of cold compresses and eye washes with tear substitute. Allergic conjunctivitis also has been successfully treated with topical mast cell stabilizers, histamine type 1 (H1) receptor antagonists, and topical nonsteroidal anti-inflammatory drugs. Systemic antihistamines may be useful in prolonged allergic conjunctivitis. In severe cases, a short course of topical corticosteroids may be required to afford symptomatic relief.

**Infectious Conjunctivitis**

The agents of infectious conjunctivitis include bacteria, viruses, gonorrhea, and chlamydia. Infections may spread from areas adjacent to the conjunctiva or may be blood-borne, such as in measles or chickenpox. Newborns can contract conjunctivitis during the birth process.

**Bacterial Conjunctivitis.** Bacterial conjunctivitis may present as a hyperacute, acute, or chronic infection. Hyperacute conjunctivitis is a severe, sight-threatening ocular infection. The infection has an abrupt onset and is characterized by a copious amount of yellow-green drainage. The symptoms, which typically are progressive, include conjunctival redness, chemosis (swelling around the cornea), lid swelling, and tender, swollen preauricular lymph nodes (Fig. 23.7). The most common causes of hyperacute purulent conjunctivitis are Neisseria gonorrhoeae and Neisseria meningitidis, with N. gonorrhoeae being the most common. Gonococcal ocular infections left untreated result in corneal ulceration with ultimate perforation, and sometimes permanent loss of vision. Diagnostic methods include immediate Gram staining of ocular specimens and special cultures for Neisseria species. Treatment includes systemic antibiotics supplemented with ocular antibiotics. Because of the increasing prevalence of penicillin-resistant N. gonorrhoeae, antibiotic choice should be determined by current information regarding antibiotic sensitivity.

Acute bacterial conjunctivitis typically presents with burning, tearing, and mucopurulent or purulent discharge. Common agents of bacterial conjunctivitis are Streptococcus pneumoniae, S. aureus, and Haemophilus influenzae. The eyelids are sticky, with possible excoriation of the lid margins.
Viral epidemic keratoconjunctivitis is caused by adenoviruses types 8, 19, 29, and 37. It presents with marked discomfort and is highly contagious, with rapid spread from person to person. The disease lasts at least 2 weeks and may be complicated by visual symptoms due to epithelial and subepithelial involvement. Topical antibiotics are ineffective in controlling the inciting viral agent, but may be used to prevent secondary bacterial infection. The most important aspect of treatment is education regarding the highly transmissible nature of the infection. Instructions should include the need for scrupulous handwashing and avoiding the shared use of eyedroppers, eye makeup, goggles, and towels. People who use contact lenses should avoid them and wear prescription glasses instead.

Chlamydial Conjunctivitis. Chlamydial conjunctivitis is usually a benign suppurative conjunctivitis transmitted by the type of Chlamydia trachomatis (serotypes D through K) that causes sexually transmitted infections. It is spread by contaminated genital secretions and occurs in newborns of mothers with C. trachomatis infections of the birth canal. It also can be contracted through swimming in unchlorinated pools. The incubation period varies from 5 to 12 days, and the disease may last for several months if untreated. The infection is usually treated with appropriate oral antibiotics. A more serious form of infection is caused by a different strain of C. trachomatis (serotypes A, B, and C). This form of chlamydial infection affects the conjunctiva and causes ulceration and scarring of the cornea. It is the leading cause of preventable blindness in the world. Although the agent is widespread, it is seen mostly in developing countries, particularly those of Africa, Asia, and the Middle East. It is transmitted by direct human contact, contaminated objects (fomites), and flies.

Chlamydial Conjunctivitis. Chlamydial conjunctivitis is usually a benign suppurative conjunctivitis transmitted by the type of Chlamydia trachomatis (serotypes D through K) that causes sexually transmitted infections. It is spread by contaminated genital secretions and occurs in newborns of mothers with C. trachomatis infections of the birth canal. It also can be contracted through swimming in unchlorinated pools. The incubation period varies from 5 to 12 days, and the disease may last for several months if untreated. The infection is usually treated with appropriate oral antibiotics.

More serious form of infection is caused by a different strain of C. trachomatis (serotypes A, B, and C). This form of chlamydial infection affects the conjunctiva and causes ulceration and scarring of the cornea. It is the leading cause of preventable blindness in the world. Although the agent is widespread, it is seen mostly in developing countries, particularly those of Africa, Asia, and the Middle East. It is transmitted by direct human contact, contaminated objects (fomites), and flies.

Viral Conjunctivitis. Etiologic agents of viral conjunctivitis include adenoviruses, herpesviruses, and enteroviruses. One of the most common causes of viral conjunctivitis is adenovirus type 3. The infection, which causes generalized conjunctival hyperemia, copious tearing, and minimal exudate, is usually accompanied by pharyngitis, fever, and malaise (Fig. 23.8). Children are affected more often than adults. Swimming pools contaminated because of inadequate chlorination are common sources of infection.

Mr. Pall had not had conjunctivitis previously, but living in a college dormitory would increase his risk of picking it up easily. He also mentioned that he had a head cold (upper respiratory infection) for several days duration and could have infected his eye himself from cross contact with the nasal drainage from his upper respiratory infection. Most likely, of the three common bacteria (Streptococcus pneumoniae, S. aureus, and H. influenzae) that cause conjunctivitis, Mr. Pall has S. pneumoniae. Because of the irritation from the contacts and cigarette smoke at the party the evening before, Mr. Pall may have touched his eyes frequently, therefore infecting the conjunctiva.
and *C. trachomatis*.\(^5,11\) Epidemiologically, these infections reflect those sexually transmitted infections most common in a particular area. Once the most common form of conjunctivitis in the newborn, gonococcal ophthalmia neonatorum now has an incidence of 0.3 per 1000 live births in the United States.\(^11\) In comparison, *C. trachomatis* ophthalmia neonatorum has an incidence of 8.2 per 1000 live births.\(^11\) To prevent gonococcal ophthalmia, 0.5% erythromycin ointment or 1% silver nitrate drops are applied immediately after birth. Silver nitrate instillation may cause mild, self-limited conjunctivitis.

Signs of ophthalmia neonatorum include redness and swelling of the conjunctiva, swelling of the eyelids, and discharge, which may be purulent. The conjunctivitis caused by silver nitrate occurs within 6 to 12 hours of birth and clears within 24 to 48 hours. The incubation period for *N. gonorrhoeae* is 2 to 5 days and for *C. trachomatis*, 5 to 14 days.\(^12\) Infection should be suspected when conjunctivitis develops 48 hours after birth. Ophthalmia neonatorum is a potentially blinding condition, and it can cause serious and potentially systemic manifestations. It requires immediate diagnosis and treatment.

### Disorders of the Cornea

At the anterior part of the eyeball, the outer covering of the eye is modified to form the transparent cornea, which bulges anteriorly from its junction with the sclera (Fig. 23.9). A major part of the refraction (i.e., bending) of light rays and focusing of vision occurs in the cornea. Three layers of tissue form the cornea:

1. An extremely thin outer epithelial layer, which is continuous with the bulbar conjunctiva
2. A middle layer called the *substantia propria* or *stroma*
3. An inner endothelial layer, which lies next to the aqueous humor of the anterior chamber\(^13\)

The substantia propria is composed of regularly arranged collagen bundles embedded in a mucopolysaccharide matrix.

---

**FIGURE 23.9** (A) Transverse section of the eyeball. (B) Enlargement of the anterior and posterior chambers of the eye, showing the layers of the cornea, the structures of the iris, and aqueous drainage system (trabecular meshwork, canal of Schlemm), and the ciliary process and ciliary muscle.
This organization of the collagen fibers, which makes the substantia propria transparent, is necessary for light transmission. Hydration within a limited range is necessary to maintain the spacing of the collagen fibers and transparency. The three layers of the cornea are separated by two important basement membranes: Bowman and Descemet membranes. Bowman membrane, which lies between the corneal epithelium and stoma, acts as a barrier to infection. It does not regenerate. If damaged, an opaque scar forms that can impair vision. Descemet membrane, which lies between the corneal endothelium and stroma, has a feltlike appearance and consists of interwoven fibers and pores. Unlike Bowman membrane, it regenerates readily after injury.

The cornea is avascular and obtains its nutrient and oxygen supply by diffusion from blood vessels of the adjacent sclera, from the aqueous humor at its deep surface, and from tears. The corneal epithelium is heavily innervated by sensory neurons (trigeminal nerve [CN V], ophthalmic division [CN V1]). Epithelial damage causes discomfort that ranges from a foreign body sensation and burning of the eyes to severe, incapacitating pain. Reflex lacrimation is common.

Disorders of the cornea include trauma, inflammation and infection, abnormal corneal deposits, and degenerative processes such as arcus senilis. Diagnosis of corneal disorders is based on history of trauma, medication use, and signs and symptoms associated with corneal irritation and disease.15 Because of the discomfort involved, examination of the eye is often eased by instillation of a local anesthetic agent. Fluorescein staining can be used to outline an ulcerated area. The biomicroscope (slit lamp) is used for proper examination of the cornea. In cases of an infectious etiology, scrapings from the ulcer are obtained for staining and culture studies.

**Corneal Trauma**

The integrity of the epithelium and the endothelium is necessary to maintain hydration of the cornea within a limited range. Damage to either structure leads to edema and loss of transparency. Among the causes of corneal edema is the prolonged wearing of contact lenses, which can deprive the epithelium of oxygen, disrupting its integrity. Corneal edema also occurs after a sudden rise in intraocular pressure. With corneal edema, the cornea appears dull, uneven, and hazy. In addition, visual acuity decreases and iridescent vision (i.e., rainbows around lights) occurs.

Trauma that causes abrasions of the cornea can be extremely painful, but if minor, the abrasions usually heal in a few days. The epithelial layer can regenerate, and small defects heal without scarring. If the stroma is damaged, healing occurs more slowly, and the danger of infection is increased. Injuries to the Bowman membrane and the stromal layer heal with scar formation that impairs the transmission of light.

**Keratitis**

Keratitis refers to inflammation of the cornea. It can be caused by infections, misuse of contact lenses, hypersensitivity reactions, ischemia, trauma, defects in tearing, and interruption in sensory innervation, as occurs with local anesthesia. Scar tissue formation due to keratitis is the leading cause of blindness and impaired vision throughout the world. Most of this vision loss is preventable if the condition is diagnosed early and appropriate treatment is begun.

Keratitis can be divided into two types: nonulcerative, in which all the layers of the epithelium are affected but the epithelium remains intact, and ulcerative, in which parts of the epithelium, stroma, or both are destroyed. Nonulcerative or interstitial keratitis is associated with many diseases, including syphilis, tuberculosis, and lupus erythematosus. It also may result from a viral infection entering through a small defect in the cornea. Treatment is usually topical antibiotics and, possibly, anti-inflammatory agents.8

Causes of ulcerative keratitis include infectious agents such as those causing conjunctivitis (e.g., *Staphylococcus, S. pneumoniae, Chlamydia*), exposure trauma, and use of extended-wear contact lenses. Bacterial keratitis is aggressive and demands immediate care. Exposure trauma may result from deformities of the lid, paralysis of the lid muscles, or severe exophthalmos. Mooren ulcer is a chronic, painful, indolent ulcer that occurs in the absence of infection. It is usually seen in older adults and may affect both eyes. Although the cause is unknown, an autoimmune origin is suspected.

**Herpes Simplex Keratitis.** Herpes simplex virus (HSV) keratitis with stromal scarring is the leading cause of corneal ulceration and blindness in the United States.14 Most cases are caused by HSV type 1, the cause of labial or lip infections. However, in neonatal infections acquired during passage through the birth canal, approximately 80% are caused by HSV type 2 (the cause of genital herpes). The disease can occur as a primary or recurrent infection.15 Primary epithelial infections are the optical counterpart of labial herpes with similar immunologic and pathologic features as well as a similar time course. During childhood, mild primary HSV infection may go unnoticed. After the initial primary infection, the virus may persist in a quiescent or latent state in the trigeminal ganglion and possibly in the cornea without causing signs of infection.

Recurrent infection may be precipitated by various poorly understood, stress-related factors that reactivate the virus. Involvement is usually unilateral. The first symptoms are irritation, photophobia, and tearing. Some reduction in vision may occur when the lesion affects the central part of the cornea. Because corneal anesthesia occurs early in the disease, the symptoms may be minimal, and the person may delay seeking medical care. A history of fever blisters or other herpetic infection is often noted, but corneal lesions may be the only sign of recurrent herpes infection. Most typically, the corneal lesion involves the epithelium and has a typical branching pattern. These epithelial lesions heal without scarring. Herpetic lesions that involve the stromal layer of the cornea produce increasingly severe corneal opacities. Although previously thought to be a purely immunologic response to viral particles or virally induced cellular changes, there is increasing evidence that infection due to active viral particles can occur in stromal
and possibly endothelial cells, as well as other tissues in the anterior segment such as the iris and trabecular endothelium.

The treatment of HSV keratitis focuses on eliminating viral replication in the cornea while minimizing the damaging effects of the inflammatory process. It involves the use of epithelial debridement and drug therapy. Debridement is used to remove the virus from the corneal epithelium. Topical antiviral agents such as trifluridine drops, vidarabine or acyclovir ointment, or ganciclovir gel are used to promote healing. Oral antiviral agents (e.g., acyclovir) are a crucial adjunct in treatment of severe keratitis and as prophylaxis against recurrence, particularly in persons with compromised immune function. Although corticosteroids may control the damaging inflammatory responses, they do so at the expense of facilitating viral replication. With a few exceptions, their use is contraindicated.

**Varicella–Zoster Ophthalmicus.** Herpes zoster or shingles is a relatively common infection caused by herpesvirus type 3, the same virus that causes varicella (chickenpox). It occurs when the varicella virus, which has remained dormant in the neurosensory ganglia since the primary infection, is reactivated. Herpes ophthalmicus, which represents 10% to 25% of all cases of herpes zoster, occurs when reactivation of the latent virus occurs in the ganglia of the ophthalmic division of the trigeminal nerve. Immunocompromised people, particularly those with human immunodeficiency virus (HIV) infection, are at higher risk for developing herpes zoster ophthalmicus than those with a normally functioning immune system. Herpes zoster ophthalmicus usually presents with malaise, fever, headache, and burning and itching of the periorbital area. These symptoms commonly precede the ocular eruption by a day or two. The rash, which is initially vesicular, becomes pustular and then crusting. Involvement of the tip of the nose and lid margins indicates a high likelihood of ocular involvement. Ocular signs include conjunctivitis, keratitis, and anterior uveitis, often with elevated intraocular pressure. People with corneal disease present with varying degrees of decreased vision, pain, and sensitivity to light.

Treatment includes the use of high-dose oral antiviral drugs (i.e., acyclovir, valacyclovir, famciclovir). Initiation of treatment within the first 72 hours after the appearance of the rash reduces the incidence of ocular complications but not the postherpetic neuralgia.

**Acanthamoeba Keratitis.** Acanthamoeba is a free-living protozoan in contaminated water frequented by travelers. Acanthamoeba keratitis is a rare but serious and sight-threatening complication of exposure from continuous wearing of soft contact lenses, either extended-wear or those worn overnight beyond doctor-recommended periods, or when poor disinfection techniques are used. It also may occur in non–contact lens wearers after exposure to contaminated water or soil. It is characterized by pain that is disproportionate to the clinical manifestations, redness of the eye, and photophobia. The disorder commonly is misdiagnosed as herpes keratitis or fungal keratitis. Diagnosis is confirmed by scrapings and culture with specially prepared medium. In the early stages of infection, epithelial debridement may be beneficial. Treatment includes intensive use of topical antibiotics. However, the organism may encyst within the corneal stroma, making treatment more difficult. Keratoplasty may be necessary in advanced disease to arrest the progression of the infection.

**Abnormal Corneal Deposits**

The cornea frequently is the site for deposition of abnormal metabolic products. In hypercalcemia, calcium salts can precipitate in the cornea, producing a cloudy band keratopathy. Cystine crystals are deposited in cystinosin, cholesterol esters in hypercholesterolemia, and a golden ring of copper (i.e., Kayser-Fleischer ring) in hepatolenticular degeneration due to Wilson disease. Pharmacologic agents, such as chloroquine, can result in crystal deposits in the cornea.

Arcus senilis is an extremely common, bilateral, benign corneal degeneration that may occur at any age but is more common in the elderly. It consists of a grayish-white infiltrate, approximately 2 mm wide, which occurs at the periphery of the cornea. It may represent an extracellular lipid infiltration and commonly is associated with hyperlipidemia so lipid studies should be done if found in people under the age of 50. Arcus senilis does not produce visual symptoms, and there is no treatment necessary for this finding in older adults.

**Corneal Transplantation**

Advances in ophthalmologic surgery permit corneal transplantation using a young cadaver cornea and it is the most commonly performed and successful human transplant procedure. Unlike kidney or heart transplantation procedures, which are associated with considerable risk of rejection of the transplanted organ, corneal transplants entail minimal danger of rejection. The low rejection rate is due to several factors: The cornea is avascular, including lymphatics, thereby limiting perfusion by immune elements; major histocompatibility complexes (class II) are virtually absent in the cornea; antigen-presenting cells are not present in great numbers; the cornea secretes immunosuppressive factors; and corneal cells secrete substances (e.g., Fas ligand) that protect against apoptosis, thereby minimizing inflammation.

**Disorders of the Uveal Tract**

The middle vascular layer, or uveal tract, is an incomplete ball with gaps at the pupil and the optic nerve. The pigmented uveal tract has three distinct regions: the choroid, ciliary body, and the iris. The choroid is a highly vascular, dark brown membrane that forms the posterior five sixths of the uveal tract. Its blood vessels provide nourishment for the other layers of the eyeball. Its brown pigment, produced by melanocytes, absorbs light within the...
nervous system producing pupillary constriction or miosis and by the autonomic nervous system, with the parasympathetic which controls the size of the pupillary opening, is controlled

Contraction or relaxation of the sphincter and radial muscles that compose the sphincter muscle of the pupil. The anterior layer of the iris forms an irregular anterior surface, containing many fibroblasts and melanocytes. Eye color differences result from the density of the pigment. The amount of pigment decreases from that found in dark brown eyes through shades of brown and green to that found in blue eyes.

Several mutations affect the pigment of the uveal tract, including albinism. Albinism is a genetic (autosomal recessive trait) deficiency of tyrosinase, the enzyme needed for the synthesis of melanin by the melanocytes. Tyrosinase-negative albinism, also called classic albinism, is characterized by an absence of tyrosinase. Affected people have white hair, pink skin, and light blue eyes. In these people, excessive light penetrates the unpigmented iris and choroid and, to some extent, the anterior sclera. Their photoreceptors are flooded with excess light, and visual acuity is markedly reduced. Excess stimulation of the photoreceptors at normal or high illumination levels is experienced as painful photophobia, a symptom of many disease processes.

Uveitis

Inflammation of the entire uveal tract, which supports the lens and neural components of the eye, is called uveitis. Uveitis is caused by infectious (virus, bacteria, fungi, or parasite) or noninfectious (autoimmune, malignant, or idiopathic) agents. One type of noninfectious etiology, autoimmune, results from an inflammatory disorder of ocular tissue with clinical features in common and an immunologically based cause. A serious consequence of uveitis can be the involvement of the underlying retina. Parasitic invasion of the choroid can result in local atrophic changes that usually involve the retina; examples include toxoplasmosis and histoplasmosis. Metastatic uveal tumors from malignancies such as breast, lung, and colon cancers have been documented. Primary uveal lymphoma is not common but occurs and requires radiation treatment.1,16

The Pupil and Pupillary Reflexes

Contraction or relaxation of the sphincter and radial muscles of the iris controls changes in pupil size. The pupillary reflex, which controls the size of the pupillary opening, is controlled by the autonomic nervous system, with the parasympathetic nervous system producing pupillary constriction or miosis and the sympathetic nervous system producing pupillary dilation or mydriasis. The sphincter muscle that produces pupillary constriction is innervated by postganglionic parasympathetic neurons of the ciliary ganglion and other scattered ganglion cells between the scleral and choroid layers. Part of the oculomotor (CN III) nucleus is called the Edinger-Westphal nucleus.17 This autonomic nucleus, found in the midbrain, provides the preganglionic innervation for these parasympathetic axons. Pupillary dilation by the radial muscles is provided by sympathetic innervation under excitatory descending control from the hypothalamus. Innervation is derived from preganglionic neurons in the upper thoracic cord, which send axons along the sympathetic chain to synapse with postganglionic neurons in the superior ciliary ganglion. Postganglionic fibers travel along the surfaces of the carotid and smaller arteries to reach the eye.

A region in the midbrain called the pretectum controls the pupillary reflex. Pretectal areas on each side of the brain are connected, explaining the binocular aspect of the light reflex. The afferent stimuli for pupillary constriction arise in the ganglionic cells of the retina and are transmitted to the pretectal nuclei at the junction of the thalamus and the midbrain, and from there to preganglionic neurons in the oculomotor (CN III) nuclei (Fig. 23.10).

Shining a penlight into one eye of the person tests normal function of the pupillary reflex mechanism. To avoid a change in pupil size due to accommodation, ask the person to stare into the distance. A rapid constriction of the pupil exposed to light should occur; this is called the direct pupillary light reflex. Because the reflex is normally bilateral, the contralateral pupil also should constrict, a reaction called the consensual pupillary light reflex. The circuitry of the light reflex is partially separated from the main optic pathway. This is illustrated by the fact that the pupillary reflex remains unaffected when lesions to the optic radiations or the visual cortex occur.

Integrity of the dual autonomic control of pupillary diameter is vulnerable to trauma, tumor enlargement, or vascular disease. With diffuse damage to the forebrain involving the thalamus and hypothalamus, the pupils are typically small but respond to light. Damage to the CN III nucleus results in permanent pupillary dilation in the affected eye. Lesions affecting the cervical spinal cord or the ascending sympathetic ganglionic chain in the neck or internal carotid artery (e.g., Horner syndrome) can interrupt the sympathetic control of the iris dilator muscle, resulting in permanent pupillary constriction. Tumors of the orbit that compress structures behind the eye can eliminate all pupillary reflexes, usually before destroying the optic nerve.

Pharmacologic agents can also differentially affect pupillary size. Bilateral pupillary constriction is characteristic of opiate usage. Pupillary dilation results when topical parasympathetic blocking agents, such as atropine, are applied and sympathetic pupillodilatory function is left unopposed. Sympathomimetic agents can enhance dilation. Ophthalmologists and optometrists use these medications to facilitate the examination of the transparent media and fundus
of the eye. Miotic drugs (e.g., pilocarpine), which are used in the treatment of angle-closure glaucoma (to be discussed), produce pupil constriction and in that manner facilitate aqueous humor circulation.

**IN SUMMARY**

The conjunctiva lines the inner surface of the eyelids and covers the optic globe to the junction of the cornea and sclera. Conjunctivitis, also called red eye or pink eye, may result from bacterial or viral infection, allergens, chemical agents, physical agents, or radiant energy. It is important to differentiate between redness caused by conjunctivitis and that caused by more serious eye disorders, such as acute glaucoma or corneal lesions.

Keratitis, or inflammation of the cornea, can be caused by infections, hypersensitivity reactions, ischemia, trauma, defects in tearing, or trauma. Trauma or disease that involves the stromal layer of the cornea heals with scar formation and permanent opacification. These opacities interfere with the transmission of light and may impair vision.

The uveal tract is the middle vascular layer of the eye. It contains melanocytes that prevent diffusion of light through the wall of the optic globe. Inflammation of the uveal tract (uveitis) can affect visual acuity.

The pupillary reflex, which controls the size of the pupil, is controlled by the autonomic nervous system. The parasympathetic nervous system controls pupillary constriction, and the sympathetic nervous system controls pupillary dilation.

Glaucoma comprises a group of conditions that produce an elevation in intraocular pressure. If left untreated, the increased pressure may cause ischemic and compressive degeneration of the optic nerve, leading to progressive blindness. It is one of the leading causes of preventable blindness in North America. The condition is often asymptomatic and, therefore, is undiagnosed in nearly 50% of the 3 million Americans, resulting in a significant loss of peripheral vision for the affected person before he or she seeks medical evaluation and treatment.18

**Control of Intraocular Pressure**

The intraocular pressure is largely regulated by the aqueous humor, which fills the anterior and posterior chambers of the eye. The aqueous humor is produced by the ciliary body and passes from the posterior chamber through the pupil into the anterior chamber18 (Fig. 23.11A). Aqueous humor leaves...
Anterior chamber
Pupil
Iris
Posterior chamber
Canal of Schlemm
Capillaries
Trabecular meshwork
Cornea
Lens

FIGURE 23.11  •  (A) Normally, aqueous humor, which is secreted in the posterior chamber, gains access to the anterior chamber by flowing through the pupil. In the angle of the anterior chamber, it passes through the canal of Schlemm into the venous system. (B) In open-angle glaucoma, the outflow of aqueous humor is obstructed at the trabecular meshwork. (C) In angle-closure glaucoma, the aqueous humor encounters resistance to flow through the pupil. Increased pressure in the posterior chamber produces a forward bowing of the peripheral iris, so that the iris blocks the trabecular meshwork.

The pressure of the aqueous humor results from a balance of several factors, including the rate of aqueous secretion, the resistance to flow between the iris and the ciliary body, and the resistance to resorption at the trabecular region of the sclera at the iridocorneal angle. Normally, the rate of aqueous production is equal to the rate of aqueous outflow, and the intraocular pressure is maintained within a normal range of 9 to 21 mm Hg.8,18

Tonometry is the measurement of intraocular pressure. The most accurate instrument used is the Goldman applanation tonometer, which is attached to a slit lamp and measures the force required to flatten a fixed area on the cornea. Central corneal thickness, which can be measured by either optical or ultrasonic methods, is thought to influence the accuracy of measurement, with intraocular pressure being overestimated in eyes with a thick cornea and underestimated in eyes with a thin cornea. Another type of tonometer, the noncontact ("air-puff") tonometer, which uses the rebound force of a small puff of air blown against the cornea to estimate the intraocular pressure, is not as accurate as the applanation tonometer. However, this method does not require anesthetic drops because no instrument touches the eye. It is therefore more easily used by technicians and is useful in screening programs.19

Glaucoma

Glaucoma usually results from congenital or acquired lesions of the anterior segment of the eye that mechanically obstruct aqueous outflow. Glaucoma is commonly classified as open-angle (i.e., wide-angle) or angle-closure (i.e., narrow-angle) glaucoma, depending on the location of the compromised outflow, and may occur as a primary or secondary disorder. Primary glaucoma occurs without evidence of preexisting ocular or systemic disease. Secondary glaucoma can result from inflammatory processes that affect the eye, from tumors, or from blood cells of trauma-produced hemorrhage that obstruct the outflow of aqueous humor.

In people with glaucoma, temporary or permanent impairment of vision results from degenerative changes in the retina and optic nerve and from corneal edema and opacification. Damage to optic nerve axons in the region of the optic nerve can be recognized on ophthalmoscopic examination. The normal optic disk has a central depression called the optic cup. With progressive atrophy of axons caused by increased intraocular pressure, pallor of the optic disk develops, and the size and depth of the optic cup increase. Because changes in the optic cup precede visual field loss, regular ophthalmoscopic examinations are important for detecting eye changes that occur with increased intraocular pressure. Many attempts...
have been made to quantify the optic disk changes in people with glaucoma using various photographic techniques and, more recently, scanning laser imaging systems.

Advances in computer technology allow detection and quantification of visual changes due to glaucoma. These tests of vision include white-on-white and blue-on-yellow visual field testing, testing of contrast sensitivity, and dark adaptation. Scanning laser technology and optical coherence tomography tests can detect damage to retinal ganglion axons before visual field loss occurs.

**Open-Angle Glaucoma**

Primary open-angle glaucoma is the most common form of glaucoma. The condition is characterized by an abnormal increase in intraocular pressure that occurs without obstruction at the iridocorneal angle, hence the name open-angle glaucoma. Instead, it usually occurs because of an abnormality of the trabecular meshwork that controls the flow of aqueous humor into the canal of Schlemm (see Fig. 23.11B). Secondary open-angle glaucoma occurs as a result of other conditions, including the formation of red cell fragments after trauma and iris pigment epithelial granules that may clog the trabecular meshwork.

The condition is usually asymptomatic and chronic, causing progressive damage to the optic nerve and visual field loss unless it is appropriately treated. Elevated intraocular pressure is a primary factor for open-angle glaucoma, but it is not the only diagnostic factor. Some people maintain a higher intraocular pressure without evidence of optic nerve damage or visual field loss, demonstrating a condition described as glaucoma suspect or ocular hypertension. It is questionable whether damage to the optic nerve results from excessive intraocular pressure, decreased blood flow to the optic nerve, or both factors.

**Etiology.** The etiology of primary open-angle glaucoma remains unclear. Major risk factors for this disorder include an age of 40 years and older, black race, a positive first-degree family history, myopia, and increased intraocular pressure. Other risk factors with moderate to fair epidemiologic evidence include hypertension, type 2 diabetes, hyperthyroidism, migraine headaches, and sleep apnea. In some people, the use of moderate amounts of topical or inhaled corticosteroid medications can cause an increase in intraocular pressure. Sensitive people also may sustain an increase in intraocular pressure with the use of systemic corticosteroid drugs. There is emerging evidence that central corneal thickness is also an important predictor for the development of primary open-angle glaucoma, and it may be a relevant predictor of both glaucoma progression and response to intraocular pressure–lowering drugs.

**Diagnosis.** Diagnostic methods include applanation tonometry, ophthalmoscopic visualization of the optic nerve, and central visual field testing. Measurement of intraocular pressures provides a means of assessing glaucoma risk. Because the condition is usually asymptomatic, persons at risk for open-angle glaucoma should have regular direct ophthalmoscopic examinations, on both eyes, concentrating on the optic disk. Optic disk changes frequently are noted before visual field defects become apparent. Periodic stereoscopic assessment of the optic disk by an eye care provider trained in the detection of glaucoma is strongly recommended for at-risk patients.

**Treatment.** The elevation in intraocular pressure in people with open-angle glaucoma is usually treated pharmacologically or, in cases where pharmacologic treatment fails, by increasing aqueous outflow through a surgically created pathway. Drugs used in the long-term management of glaucoma fall into five classes: β-adrenergic antagonists, prostaglandin analogs, adrenergic agonists, carbonic anhydrase inhibitors, and cholinergic agonists. Most glaucoma drugs are applied topically. However, systemic side effects may occur. When treatment with one drug does not reduce the intraocular pressure to the target level, a drug from a different class may be used or a second medication may be added as adjunctive therapy.

Topical β-adrenergic antagonists are usually the drugs of first choice for lowering intraocular pressure. The β-adrenergic antagonists are thought to lower intraocular pressure by decreasing aqueous humor production in the ciliary body. Systemic adsorption of these eye drops can cause bradycardia and bronchospasm in persons with asthma. Carbonic anhydrase inhibitors reduce the secretion of aqueous humor by the ciliary epithelium. The topical carbonic anhydrase inhibitors (dorzolamide and brinzolamide) are often used as adjunctive therapy, but rarely as initial therapy. Selective α₁-adrenergic agonists (i.e., brimonidine and apraclonidine) increase aqueous outflow in addition to decreasing aqueous production. They are effective as an adjunctive, or occasionally as a primary, treatment agent. Local ocular allergy often limits the usefulness of apraclonidine.

Several classes of drugs increase aqueous outflow. Prostaglandins are locally acting substances found in most tissues. At low concentrations, prostaglandin F₂α increases the outflow of aqueous humor through the iris root and ciliary body, either by decreasing the extracellular matrix or by relaxing the ciliary musculature. Latanoprost, a topical pros taglandin analog, is now one of the most frequently prescribed glaucoma drugs. Acetylcholine is the postganglionic neuro mediator for the parasympathetic nervous system; it increases aqueous outflow through contraction of the ciliary muscle and pupillary constriction (miosis). Pilocarpine, a parasympathomimetic miotic and once the mainstay of treatment, has largely been replaced by newer and more effective drugs.

When a reduction in intraocular pressure cannot be maintained through pharmacologic methods, laser or surgical trabeculoplasty may become necessary. With laser trabeculoplasty, the microbumps created by the laser treatment scar rather than penetrate the trabecular meshwork, a process thought to enlarge the outflow channels by increasing the tension exerted on the trabecular meshwork. Cryotherapy, diathermy, and high-frequency ultrasound may be used in some cases to destroy the ciliary epithelium and reduce aqueous humor production.
Angle-Closure Glaucoma

Angle-closure glaucoma results from occlusion of the anterior chamber angle by the iris (see Fig. 23.11C). It is most likely to develop in eyes with preexisting shallow anterior chambers. An acute attack is often precipitated by pupillary dilation, which causes the iris to thicken, thus blocking the circulation between the posterior and anterior chambers. Angle-closure glaucoma usually occurs as the result of an inherited anatomic defect that causes a shallow anterior chamber. It is seen more commonly in people of Asian or Inuit (Eskimo) descent and in people with hypermetropic eyes. This defect is exaggerated by the anterior displacement of the peripheral iris that occurs in older adults because of the increase in lens thickness that occurs with aging.

Clinical Manifestations. Symptoms of acute angle-closure glaucoma are related to sudden, intermittent increases in intraocular pressure. These occur after prolonged periods in the dark, emotional upset, and other conditions that cause extensive and prolonged dilation of the pupil. Administration of pharmacologic agents such as atropine that cause pupillary dilation (mydriasis) also can precipitate an acute episode of increased intraocular pressure in persons with the potential for angle-closure glaucoma. Attacks of increased intraocular pressure are manifested by ocular pain and blurred or iridescent vision caused by corneal edema. The pupil may be enlarged and fixed. Symptoms are often spontaneously relieved by sleep and conditions that promote pupillary constriction. With repeated or prolonged attacks, the eye becomes reddened, and edema of the cornea may develop, giving the cornea a hazy appearance. A unilateral, often excruciating, headache is common. Nausea and vomiting may occur, causing the headache to be confused with migraine.

Some people with congenitally narrow anterior chambers never develop symptoms, and others develop symptoms only in older age. Because of the dangers of vision loss, those with narrow anterior chambers should be warned about the significance of blurred vision, halos, and ocular pain. Sometimes, decreased visual acuity and an unreactive pupil may be the only clues to angle-closure glaucoma in older adults.

Diagnosis and Treatment. The depth of the anterior chamber can be evaluated by side/shadow illumination or by a technique called gonioscopy. Gonioscopy uses a special contact lens and mirrors or prisms to view and measure the angle of the anterior chamber. The side/shadow illumination method uses only a penlight. The light source is held at the temporal side of the eye and directed horizontally across the iris. In people with a normal-sized anterior chamber, the light passes through the chamber to illuminate both halves of the iris. In people with a narrow anterior chamber, only the half of the iris adjacent to the light source is illuminated, whereas a shadow is cast on the half of the iris opposite the light source.

Acute angle-closure glaucoma is an ophthalmic emergency. Treatment is initially directed at reducing the intraocular pressure, usually with pharmacologic agents. Once the intraocular pressure is under control, a laser peripheral iridotomy is performed to create a permanent opening between the anterior and posterior chambers, allowing the aqueous humor to bypass the pupillary block. The anatomic abnormalities responsible for angle-closure glaucoma are usually bilateral, and prophylactic surgery is often performed on the other eye.

Congenital and Infantile Glaucoma

There are several types of childhood glaucoma, including congenital glaucoma that is present at birth and infantile glaucoma that develops during the first 2 to 3 years of life. As with glaucoma in adults, childhood glaucoma can occur as a primary or secondary disorder.

Etiology and Pathophysiology. Congenital glaucoma is caused by a disorder in which the anterior chamber retains its fetal configuration, with aberrant trabecular meshwork extending to the root of the iris, or is covered by a membrane. In general it has a much poorer prognosis than infantile glaucoma. Primary infantile glaucoma occurs in approximately 1 in 10,000 live births but accounts for 2% to 15% of persons in institutions for the blind. It is bilateral in 65% to 80% of cases and occurs more commonly in boys than girls. About 10% of cases have a familial origin, and the rest are either sporadic or possibly multifactorial with reduced penetrance. The familial cases are usually transmitted as an autosomal dominant trait with potentially high penetrance. Recent studies suggest a mutation in chromosome 2 (2p21 region). This gene is expressed in the tissues of the anterior chamber of the eye, and its protein product plays an important role in the metabolism of molecules that are used in signaling pathways during the terminal stages of anterior chamber development.

Clinical Manifestations and Treatment. The earliest symptoms of congenital or infantile glaucoma are excessive lacrimation and photophobia. Affected infants tend to be fussy, have poor eating habits, and rub their eyes frequently. Diffuse edema of the cornea usually occurs, giving the eye a grayish-white appearance. Chronic elevation of the intraocular pressure before the age of 3 years causes enlargement of the entire optic globe. Early surgical treatment is necessary to prevent blindness.

IN SUMMARY

Glaucoma is a leading cause of blindness worldwide. It is characterized by conditions that cause an increase in intraocular pressure and that, if untreated, can lead to atrophy of the optic disk and progressive blindness. The aqueous humor is formed by the ciliary epithelium in the posterior chamber and flows through the pupil to the angle formed by the cornea and the iris. Here, it filters through the trabecular meshwork and enters the canal of Schlemm for return to the venous circulation. Glaucoma results from overproduction or impeded outflow of aqueous humor from the anterior chamber of the eye.
There are two types of glaucoma: open-angle and angle-closure. Open-angle glaucoma is caused by microscopic obstruction of the trabecular meshwork. Open-angle glaucoma is usually asymptomatic, and considerable loss of the visual field often occurs before medical treatment is sought. Routine screening by applanation tonometry provides one of the best means for early detection of glaucoma before vision loss has occurred. Angle-closure glaucoma is caused by a narrow anterior chamber and blockage of the outflow channels at the angle formed by the iris and the cornea. This occurs when the iris becomes thickened during pupillary dilation. Congenital glaucoma is caused by a disorder in which the anterior chamber retains its fetal configuration, with aberrant trabecular meshwork extending to the root of the iris, or is covered by a membrane. Early surgical treatment is necessary to prevent blindness.

**DISORDERS OF THE LENS AND LENS FUNCTION**

After completing this section of the chapter, you should be able to meet the following objectives:

- Describe changes in eye structure that occur with nearsighted and farsighted vision.
- Describe changes in lens structure that occur with cataract.
- Cite risk factors and visual changes associated with cataract.

The function of the eye is to transform light energy into nerve signals that can be transmitted to the cerebral cortex for interpretation. Optically, the eye is similar to a camera. It contains a lens system that focuses an inverted image, an aperture (i.e., the pupil) for controlling light exposure, and a retina that corresponds to the film and records the image.

**Disorders of Refraction and Accommodation**

The lens is an avascular, transparent, biconvex body, the posterior side of which is more convex than the anterior side. A thin, highly elastic lens capsule is attached to the surrounding ciliary body by delicate suspensory radial ligaments called zonules, which hold the lens in place (see Fig. 23.9). The tough elastic sclera, in providing for a change in lens shape, acts as a bow, and the zonule and the lens capsule act as the bowstring. The suspensory ligaments and lens capsule are normally under tension, causing the lens to have a flattened shape for distant vision. Contraction of the muscle fibers of the ciliary body narrows the diameter of the ciliary body, relaxes the fibers of the suspensory ligaments, and allows the lens to relax to a more convex shape for near vision.

When light passes from one medium to another, its velocity is decreased or increased, and the direction of light transmission is changed. This change in direction of light rays is called refraction. When light rays pass through the center of a lens, their direction is not changed. However, other rays passing peripherally through a lens are bent (Fig. 23.12A). The refractive power of a lens is usually described as the distance (in meters) from its surface to the point at which the rays come into focus (i.e., focal length). Usually, this is reported as the reciprocal of this distance (i.e., diopters). For example, a lens that brings an object into focus at 0.5 m has a refractive power of 2 diopters (1/0.5 = 2). With a fixed-power lens, the closer an object is to the lens, the further behind the lens is its focus point. The closer the object, the stronger and more precise the focusing system must be.

In the eye, the major refraction of light begins at the convex corneal surface. Further refraction occurs as light moves from the posterior corneal surface to the aqueous humor, from the aqueous humor to the anterior lens surface, from the

**FIGURE 23.12**

(A) Accommodation. The solid lines represent rays of light from a distant object, and the dotted lines represent rays from a near object. The lens is flatter for the former and more convex for the latter. In each case, the rays of light are brought to a focus on the retina.

(B) Hyperopia corrected by a biconvex lens, shown by the dotted lines.

(C) Myopia corrected by a biconcave lens, shown by the dotted lines.
Disorders of Refraction

A perfectly shaped optic globe and cornea result in optimal visual acuity, producing a sharp image in focus at all points on the retinal surface in the posterior part, or fundus, of the eye. Unfortunately, individual differences in formation and growth of the eyeball and cornea frequently result in inappropriate focal image formation. If the anterior–posterior dimension of the eyeball is too short, the image is theoretically focused posterior to (behind) the retina. This is called hyperopia or farsightedness. In such cases, the accommodative changes of the lens can bring distant images into focus, but near images become blurred. Hyperopia (Fig. 23.12B) is corrected by appropriate convex-surface lenses. If the anterior–posterior dimension of the eyeball is too long, the focus point for an infinitely distant target is anterior to the retina. This condition is called myopia or nearsightedness (Fig. 23.12C). People with myopia can see close objects without problems because accommodative changes in their lens bring near objects into focus, but distant objects are blurred. Myopia can be corrected with an appropriate concave-surface lens. Refractive corneal surgeries such as laser in situ keratomileusis (LASIK), photorefractive keratectomy, and radial keratotomy, can be performed to correct the corneal curvature to create accurate optical focus.24,25

Refractive defects of the corneal surface do not permit the formation of a sharp image. Nonuniform curvature of the refractive medium with regard to the horizontal and vertical planes is called astigmatism. Astigmatism is usually the result of an asymmetric bowing of the cornea, but it can result from defects in the cornea, lens, or the retina. Lens correction is available to sharpen focus in case of such refractive error.

Disorders of Accommodation

Because the retina is at a fixed distance from the lens, adjustability in the refractive power of the lens is needed so that a clear image is maintained as gaze is shifted from a far to a near object. The process by which the refractive power of the lens is increased, and the diverging light rays are bent more sharply, is called accommodation. Accommodation is neurologically associated with convergence of the eyes and pupillary constriction, and results from thickening of the lens through contraction of the ciliary muscle. Contraction of the ciliary muscles is controlled mainly by the parasympathetic fibers of the oculomotor CN III. In near vision, pupillary constriction (i.e., miosis) improves the clarity of the retinal image. This must be balanced against the resultant decrease in light intensity reaching the retina. During changes from near to far vision, pupillary dilation partially compensates for the reduced size of the retinal image by increasing the light entering the pupil. A third component of accommodation involves the reflex narrowing of the palpebral opening during near vision and widening during far vision.

Paralysis of the ciliary muscle, with loss of accommodation, is called cycloplegia.26,27 Pharmacologic cycloplegia is sometimes necessary to aid refractive examination of the eye, especially in small children who are unable to hold a steady degree of accommodation during the examination. Lens shape is totally controlled by the prepectal region and the parasympathetic pathways through the oculomotor nerve to the ciliary muscle. Accommodation is lost with destruction of this pathway.

The term presbyopia refers to a decrease in accommodation that occurs because of aging. The lens consists of transparent fibers arranged in concentric layers, of which the external layers are the newest and softest. No loss of lens fibers occurs with aging; instead, additional fibers are added to the outermost portion of the lens. As the lens ages, it thickens, and its fibers become less elastic, so that the range of focus or accommodation is diminished to the point where reading glasses become necessary for near vision.

Cataracts

A cataract is a lens opacity that interferes with the transmission of light to the retina. It has been estimated that 18 million people in the world are visually disabled because of cataracts.28 Cataracts are the most common cause of age-related visual loss in the world. They are found in approximately 50% of those between 65 and 74 years of age, and in 70% of those older than 75 years.1 Cataract surgery is the most common surgical procedure covered by Medicare, with more than 1 million procedures performed annually. More than 95% of people undergoing cataract surgery experience visual improvement if there is no ocular comorbidity.26,28

Causes and Types of Cataracts

The cause of cataract development is thought to be multifactorial, with different factors being associated with different types of opacities. The pathogenesis of cataracts is not completely understood. Several risk factors have been proposed, including the effects of aging, genetic influences, environmental and metabolic influences, drugs, and injury.27,28 Metabolically induced cataracts are caused by disorders of carbohydrate metabolism (diabetes) or inborn errors of metabolism. Long-term exposure to sunlight (ultraviolet B radiation) and heavy smoking have been associated with increased risk of cataract formation.29 Occasionally, cataracts occur as a developmental defect (i.e., congenital cataracts) or secondary to trauma or diseases.7,29

Cataracts can result from several drugs. Corticosteroid drugs have been implicated as causative agents in cataract formation. Both systemic and inhaled corticosteroids have been cited as risk factors.28 Other drugs associated with cataracts include the phenothiazines, amiodarone, and strong miotic ophthalmic drugs such as phospholine iodine.8 Frequent examination of lens transparency should accompany the use of these and any other medications with potential cataract-forming effects.
Traumatic Cataract. Traumatic cataracts are usually caused by foreign body injury to the lens or blunt trauma to the eye. Foreign body injury that interrupts the lens capsule allows aqueous and vitreous humor to enter the lens and initiate cataract formation. Other causes of traumatic cataract are overexposure to heat (e.g., glassblower cataract) or to ionizing radiation. The radiation dose necessary to cause a cataract varies with the amount and type of energy; younger lenses are most vulnerable.

Congenital Cataract. A congenital cataract is one that is present at birth. Among the causes of congenital cataracts are genetic defects, toxic environmental agents, and viruses such as rubella. Cataracts and other developmental defects of the ocular apparatus depend on the total dose of the agent and the embryonic stage at the time of exposure. During the last trimester of fetal life, genetically or environmentally influenced malformation of the superficial lens fibers can occur. Congenital lens opacities may occur in children of diabetic mothers.29

Most congenital cataracts are not progressive and are not dense enough to cause significant visual impairment. However, if the cataracts are bilateral and the opacity is significant, lens extraction should be done on one eye by the age of 2 months to permit the development of vision (see later section on amblyopia). If the surgery is successful, the contralateral lens should be removed soon after.

Senile Cataract. Cataracts are the most common cause of age-related vision loss in the world.29 With normal aging, the nucleus and the cortex of the lens enlarge as new fibers are formed in the cortical zones of the lens. In the nucleus, the old fibers become more compressed and dehydrated. Metabolic changes occur and lens proteins become more insoluble, and concentrations of calcium, sodium, potassium, and phosphate increase. During the early stages of cataract formation, a yellow pigment and vacuoles accumulate in the lens fibers. The unfolding of protein molecules, cross-linking of sulfhydryl groups, and conversion of soluble to insoluble proteins lead to the loss of lens transparency. The onset is gradual, and the only symptoms are increasingly blurred vision and visual distortion.

Clinical Manifestations
The manifestations of cataract depend on the extent of opacity and whether the defect is bilateral or unilateral. With the exception of traumatic or congenital cataract, most cataracts are bilateral. Age-related cataracts, which are the most common type, are characterized by increasingly blurred vision and visual distortion. Visual acuity for far and near objects decreases. Dilation of the pupil in dim light improves vision. With nuclear cataracts (those involving the lens nucleus), the refractive power of the anterior segment often increases to produce an acquired myopia. Persons with hyperopia may experience a “second sight” or improved reading acuity until increasing opacity reduces acuity. Central lens opacities may divide the visual axis and cause an optical defect in which two or more blurred images are seen. Posterior subcapsular cataracts are located in the posterior cortical layer and usually involve the central visual axis. In addition to decreased visual acuity, cataracts tend to cause light entering the eye to be scattered, thereby producing glare or the abnormal presence of light in the visual field.

Diagnosis and Treatment
Diagnosis of cataract is based on ophthalmoscopic examination and the degree of visual impairment on the Snellen vision test. On ophthalmoscopic examination, cataracts may appear as a gross opacity filling the pupillary aperture or as an opacity silhouetted against the red background of the fundus. A Snellen test acuity of 20/50 is a common requirement for drivers of motor vehicles, so tests of potential vision (i.e., the ability to see well after surgery) may be done to ensure that the visual loss can be corrected to necessary functional levels if the cataract were removed.

There is no effective medical treatment for cataract. Strong bifocals, magnification, appropriate lighting, and visual aids may be used as the cataract progresses. Surgery is the only treatment for correcting cataract-related vision loss. Surgery usually involves lens extraction and intraocular lens implantation. It is commonly performed on an outpatient basis with the use of local anesthesia. The use of extracapsular surgery, which leaves the posterior capsule of the lens intact, has significantly improved the outcomes of cataract surgery. The cataract lens is usually removed using phacoemulsification techniques.8 Phacoemulsification involves ultrasonic fragmentation of the lens into fine pieces, which then are aspirated from the eye.

One of the greatest advances in cataract surgery has been the development of reliable intraocular implants. Monofocal intraocular lenses that correct for distance vision are available, and eyeglasses may be needed for near vision, although this has been addressed by the recent introduction of multifocal intraocular lenses.

IN SUMMARY

The lens is a biconvex, avascular, colorless, and almost transparent structure suspended behind the iris. The shape of the lens is controlled by the ciliary muscle, which contracts and relaxes the zonule fibers, thus changing the tension on the lens capsule and altering the focus of the lens. Refraction, which refers to the ability to focus an object on the retina, depends on the size and shape of the eyeball and the cornea and on the focusing ability of the lens. Errors in refraction occur when the visual image is not focused on the retina because of individual differences in the size or shape of the eyeball or cornea. In hyperopia, or farsightedness, the image theoretically falls behind the retina. In myopia, or nearsightedness, the image falls in front of the retina. Accommodation is the process by which a clear image is maintained as the gaze is shifted from a far to a near object. It is associated with convergence of the
eyes and pupillary constriction, and thickening of the lens results from contraction of the ciliary muscle. Presbyopia is a change in the lens that occurs because of aging such that the lens becomes thicker and less able to change shape and accommodate for near vision.

A cataract is a lens opacity. It can occur as the result of congenital influences, metabolic disturbances, infection, injury, and aging. The most common type of cataract is the senile cataract that occurs with aging. The treatment for a totally opaque or mature cataract is surgical extraction. An intraocular lens implant may be inserted during the surgical procedure to replace the removed lens; otherwise, thick convex lenses or contact lenses are used to compensate for the loss of lens function.

Disorders of the Retina

The posterior segment, comprising five sixths of the eyeball, contains the transparent vitreous humor and the neural retina. The innermost layer of the eyeball, the fundus, is visualized through the pupil with an opthalmoscope.

Disorders of the Vitreous

Vitreous humor (i.e., vitreous body) is a colorless, amorphous biologic gel that fills the posterior cavity of the eye (see Fig. 23.2). It consists of approximately 99% water, some salts, glycoproteins, proteoglycans, and dispersed collagen fibrils. The vitreous is attached to the ciliary body and the peripheral retina in the region of the ora serrata and to the periphery of the optic disk.

Disease, aging, and injury can disturb the factors that maintain the water of the vitreous humor in suspension, causing liquefaction of the gel to occur. With the loss of gel structure, fine fibers, membranes, and cellular debris develop. When this occurs, floaters (images) can often be noticed as these substances move within the vitreous cavity during head movement. In disease, blood vessels may grow from the surface of the retina or optic disk onto the posterior surface of the vitreous, and blood may fill the vitreous cavity.

In a procedure called a vitrectomy, the removal and replacement of the vitreous with a balanced saline solution can restore sight in some people with vitreous opacities resulting from hemorrhage or vitreoretinal membrane formations that cause legal blindness. Using this procedure, a small probe with a cutting tip is used to remove the opaque vitreous and membranes. The procedure is difficult and requires complex instrumentation. It is of no value if the retina is not functional.

Disorders of the Retina

The function of the retina is to receive visual images, partially analyze them, and transmit this modified information to the brain. It is composed of two layers: the inner neural retina that contains the photoreceptors and an outer melanin-containing layer that rests on, and is firmly attached to, the choriocapillaris, the capillary layer of the choroid. A non–light-sensitive portion of the retina, along with the retinal pigment epithelium, continues anteriorly to form the posterior surface of the iris. A wavy border called the ora serrata exists at the junction between the light-sensitive and the non–light-sensitive retinas. Separating the vascular portion of the choroid from pigmented cells of the retina is a thin layer of elastic tissue, the Bruch membrane, which contains collagen fibrils in its superficial and deep portions. Cells of the pigmented layer receive their nourishment by diffusion from the choriocapillaris.

Disorders of the retina and its function include derangements of the pigment epithelium (e.g., retinitis pigmentosa), ischemic conditions caused by disorders of the retinal blood supply, disorders of the retinal vessels such as retinopathies that cause hemorrhage and the development of opacities, separation of the pigment and sensory layers of the retina (i.e., retinal detachment), abnormalities of the Bruch membrane and choroid (e.g., macular degeneration), and malignant tumors of the nuclear layer of the retina (i.e., retinoblastoma). Because the retina has no pain fibers, most diseases of the retina are painless and do not cause redness of the eye.

The Neural Retina

The neural retina is composed of three layers of neurons: a posterior layer of photoreceptors, a middle layer of bipolar cells, and an inner layer of ganglion cells that communicate with the photoreceptors (Fig. 23.13). A pattern of light on the retina falls on a massive array of photoreceptors. These photoreceptors synapse with bipolar and other interneurons before action potentials in ganglion cells relay the message to specific regions of the brain and the brain stem associated with vision. For rods, this microcircuitry involves the convergence of signals from many rods on a single ganglion cell. This arrangement maximizes spatial summation and the detection of stimulated (light versus dark) receptors. The interneurons, composed of horizontal and amacrine cells, have cell bodies in the bipolar layer, and they play an important role in modulating retinal function. A superficial marginal layer contains the axons of the ganglion cells as they collect and leave the eye through the optic nerve. These fibers lie beside the vitreous humor. Light must pass through the transparent inner layers of the sensory retina before it reaches the photoreceptors.
Photoreceptors

Two types of photoreceptors are present in the retina: rods, capable of black–white discrimination, and cones, capable of color discrimination. Both types of photoreceptors are thin, elongated, mitochondria-filled cells with a single, highly modified cilium (Fig. 23.14). The cilium has a short base, or inner segment, and a highly modified outer segment. The plasma membrane of the outer segment is tightly folded to form membranous disks (rods) or conical shapes (cones) containing visual pigment. These disks are continuously synthesized at the base of the outer segment and shed at the distal end. Discarded membranes are phagocytized by the retinal pigment cells. If this phagocytosis is disrupted, as in retinitis pigmentosa, the sensory retina degenerates.

Rods. Photoreception involves the transduction of light energy into an altered ionic membrane potential of the rod cell. Light passing through the eye penetrates the nearly transparent neural elements to produce decomposition of the photochemical substance (visual pigment) called rhodopsin in the outer segment of the rod. Light that is not trapped by a rhodopsin molecule is absorbed by the retinal pigment melanin or deeper choroid melanin. Rhodopsin consists of a protein called opsin and a vitamin A–derived pigment called retinal. During light stimulation, rhodopsin is broken down into its component parts, opsin and retinal; retinal subsequently is converted into vitamin A. The reconstitution of rhodopsin occurs during total darkness; vitamin A is transformed into retinal, and then opsin and retinal combine to form rhodopsin. Considerable stores of vitamin A are present in the retinal pigment cells and in the liver; therefore, a vitamin A deficiency must be present for weeks or months before rod function is affected.
to affect the photoreceptive process. Reduced sensitivity to light, a symptom of vitamin A deficiency, initially affects night vision; however, this is quickly reversed by injection or ingestion of the vitamin.

Rod-based vision is particularly sensitive to detecting light, especially moving light stimuli, at the expense of clear pattern discrimination. Rod vision is particularly adapted for night and low-level illumination. Dark adaptation is the process by which rod sensitivity increases to the optimum level. This requires approximately 4 hours in total or near-total darkness and is referred to as scotopic vision (night vision). During daylight or high-intensity bombardment, the concentration of vitamin A increases, whereas the concentration of the photopigment retinal decreases. During dark adaptation, an increase in synthesis of retinal from vitamin A results in a higher concentration of rhodopsin available to capture light energy.

Cones and Color Sensitivity. Cone receptors that are selectively sensitive to different wavelengths of light provide the basis for color vision. Three types of cones, or cone–color systems, respond to the blue, green, and red portions of the visible electromagnetic spectrum. This selectivity reflects the presence of one of three color-sensitive molecules to which the photochemical substance (visual pigment) is bound. The decomposition and reconstitution processes of the cone visual pigments are believed to be similar to that of the rods. The color a person perceives depends on which set of cones or combination of sets of cones is stimulated in a given image.

Cones do not have the dark adaptation capability of rods. Consequently, the dark-adapted eye is a rod receptor eye with only black-gray-white discrimination (scotopic or night vision). The light-adapted eye (photopic vision) adds the capacity for color discrimination. Rhodopsin has its maximum sensitivity in the blue-green region of the electromagnetic spectrum. If red lenses are worn in daylight, the red cones (and green cones to some extent) are in use, whereas the rods and blue cones are essentially in the dark, and therefore dark adaptation proceeds. This method is used by military and night-duty airport control tower personnel to allow adaptation to take place before they go on duty in the dark.

Macula and Fovea. An area approximately 1.5 mm in diameter near the center of the retina, called the macula lutea (i.e., “yellow spot”), is especially adapted for acute and detailed vision.30 This area is composed entirely of cones. In the central portion of the macula, the fovea centralis (foveola), the blood vessels and innermost layers are displaced to one side instead of resting on top of the cones (Fig. 23.15).

Retinitis Pigmentosa. Retinitis pigmentosa represents a group of hereditary diseases that cause slow degenerative changes in the retinal photoreceptors. The disease can be inherited as an autosomal dominant (30% to 40% of cases), autosomal recessive (50% to 60%), or sex-linked (5% to 15%) trait. With advances in genetics technology, there are now 36 known or predicted retinitis pigmentosa genes. The group of genes most commonly mutated encodes proteins in the visual cascade of the photoreceptor outer segment. Although retinitis pigmentosa is a disease usually confined to the eye, approximately 20% to 30% of people have associated nonocular disease. Usher syndrome, in which retinitis pigmentosa is associated with hearing impairment, is the most frequent of these combined syndromes. The hearing loss can be either profound, present at birth, and associated with vestibular ataxia, or moderate to mild and nonprogressive.

In typical cases, known as rod–cone retinitis pigmentosa, the rods are the predominantly affected photoreceptor cells. This generally produces a number of characteristic clinical symptoms, including night blindness, which is usually an early symptom, and bilateral symmetric loss of midperipheral fields. Although there is relative preservation of macular vision, the visual field defects gradually increase both centrally and peripherally. With progression, cone photoreceptor cells are also affected and day vision and central visual acuity are compromised. The rate of visual failure is variable.

Color Blindness. “Color blindness” is a misnomer for a condition in which people appear to confuse or mismatch colors, or experience reduced acuity for color discrimination. These people are often unaware of their defect until they attempt to discriminate between red and green traffic lights or show difficulty matching colors. Color blindness is inherited as an X-linked deficiency of a specific type of retinal photoreceptor. The most common abnormality is red-green color blindness. The deficiency is usually partial, but can be complete. Rarely are two of the color mechanisms missing; when this occurs, usually red and green are missing. Complete lack of color discrimination is rare. For such people, the world is experienced entirely as black, gray, and white.

The genetically color-blind person has never experienced the full range of normal color vision and is unaware of what he or she is missing. Color discrimination is necessary for everyday living, and color-blind people, knowingly or unknowingly, make color discriminations based on other criteria, such as brightness or position. For example, the red light of a traffic signal is always the upper light, and the green is the lower light. Color-blind people experience difficulties when brightness differences are small, and discrimination must be based on hue and saturation qualities.

Disorders of Retinal Blood Supply

The blood supply for the retina is derived from two sources: the choriocapillaris (i.e., the capillary layer of the choroid) and branches of the central retinal artery (Fig. 23.16). Oxygen
The bipolar, horizontal, amacrine, and ganglion cells, and the ganglion cell axons that gather at the optic disk, are supplied by branches of the retinal artery. The central artery of the retina is a branch of the ophthalmic artery. It enters the globe through the optic disk. Branches of this artery radiate over the entire retina, except the central fovea, which is surrounded by, but is not crossed by, arterial branches. The central artery of the retina is an end artery, meaning that it does not anastomose with other arteries. This is critical because an infarct in this artery will totally deprive distal structures of their vascular supply. Retinal veins follow a distribution parallel to the arterial branches and carry venous blood to the central vein of the retina, which exits the back of the eye through the optic disk.

Funduscopic examination of the eye with an ophthalmoscope provides an opportunity to examine the retinal blood vessels and other aspects of the retina (Fig. 23.17). Because the retina is an embryonic outgrowth of the brain and the blood vessels are to a considerable extent representative of brain blood vessels, the ophthalmoscopic examination of the fundus of the eye permits the study and diagnosis of metabolic and vascular diseases of the brain as well as pathologic processes that are specific to the retina.

Functioning of the retina, like that of other cellular portions of the CNS, depends on an oxygen supply from the vascular system. One of the earliest signs of decreased perfusion pressure in the head region is a graying-out or blackout of vision, which usually precedes loss of consciousness. This can occur during large increases in intrathoracic pressure, which interfere with the return of venous blood to the heart, as occurs with the Valsalva maneuver, with systemic hypotension, and during sudden postural changes (e.g., postural hypotension).

Ischemia of the retina occurs during general circulatory collapse. If a person survives cardiopulmonary arrest, for instance, permanently decreased visual acuity can occur as a result of edema and the ischemic death of retinal neurons. This is followed by primary optic nerve atrophy proportional to the extent of ganglionic cell death. The ophthalmic artery, the source of the central artery of the retina, takes its origin from the internal carotid artery. Intermittent retinal ischemia can accompany internal carotid or common carotid stenosis. Amaurosis fugax is characterized by transient episodes of monocular visual loss lasting 5 to 10 minutes. People with the disorder often describe a curtain coming down from above or across their vision, usually with complete return of vision within seconds or minutes. Besides the vision loss, contralateral hemiplegia or sensory deficits may accompany the episodes. The condition, commonly due to emboli, is most often the result of carotid artery disease.

**Papilledema.** The central retinal artery enters the eye through the optic papilla in the center of the optic nerve. An accompanying vein exits the eye along the same path. The entrance and exit of the central retinal artery and vein through the tough scleral tissue at the optic papilla can be compromised by any condition causing persistent increased intracranial pressure. The most common of these conditions are cerebral tumors, subdural hematomas, hydrocephalus, and malignant hypertension.

Usually, the thin-walled, low-pressure veins are the first to collapse, with the consequent backup and slowing of arterial blood flow. Under these conditions, capillary permeability increases and leakage of fluid results in edema of the optic papilla, called papilledema. The interior surface of the papilla is normally cup-shaped and can be evaluated for cupping with an ophthalmoscope. With papilledema, sometimes...
Neovascularization occurs in many conditions that impair the retinal veins, extending between the sensory retina and the pigment layer, or from vessels. They can develop from the choriocapillaris, extending between the pigment layer and the sensory layer, or from abnormal etiologies of blood or decreased flow, vascular occlusion, sickle cell disease, sarcoidosis, diabetes mellitus, and retinopathy of prematurity.33–36

Hemorrhage can be preretinal, intraretinal, or subretinal. 
Preretinal hemorrhages occur between the retina and the vitreous. These hemorrhages are usually large because the blood vessels are only loosely restricted; they may be associated with a subarachnoid or subdural hemorrhage and are usually regarded as a serious manifestation of the disorder. They usually reabsorb without complications unless they penetrate into the vitreous. 
Intraretinal hemorrhages occur because of abnormalities of the retinal vessels, diseases of the blood, increased pressure in the retinal vessels, or vitreous traction on the vessels. Systemic causes include diabetes mellitus, hypertension, and blood dyscrasias. Subretinal hemorrhages are those that develop between the choroid and pigment layer of the retina. A common cause of subretinal hemorrhage is neovascularization. Photocoagulation may be used to treat microaneurysms and neovascularization.

Light normally passes through the transparent inner portions of the sensory retina before reaching the photoreceptors. Opacities such as hemorrhages, exudate, cotton-wool spots, edema, and tissue proliferation can produce a localized loss of transparency observable with an ophthalmoscope. Exudates are opacities resulting from inflammatory processes. The development of exudates often results in the destruction of the underlying retinal pigment and choroid layer. Deposits are localized opacities consisting of lipid-laden macrophages or accumulated cellular debris. Cotton-wool spots are retinal opacities with hazy, irregular outlines. They occur in the nerve fiber layer and contain cell organelles. Cotton-wool patches are associated with retinal trauma, severe anemia, papilledema, and diabetic retinopathy.

Diabetic Retinopathy. Diabetic retinopathy is the third leading cause of blindness for all ages in the industrialized countries of the world. It ranks first as the cause of newly reported cases of blindness in people between the ages of 20 and 74 years.33 Advances in treatment have greatly reduced the risk of blindness from diabetes, but because diabetes is so common, retinopathy remains an important cause of visual impairment.

Diabetic retinopathy can be divided into two types: nonproliferative (i.e., background) and proliferative.33–35 Background or nonproliferative retinopathy is confined to the retina. It involves engorgement of the retinal veins, thickening of the capillary endothelial basement membrane, and development of capillary microaneurysms (Fig. 23.19A). Small intraretinal hemorrhages may develop and microinfarcts may occur because of glare (because of the scattering of light) is a common complaint. The most common cause of decreased vision in persons with background retinopathy is macular edema. The edema is caused primarily by the breakdown of the inner blood−retina barrier at the level of the capillary endothelium, allowing leakage of fluid and plasma constituents into the surrounding retina.
Proliferative diabetic retinopathy represents a more severe retinal change than background retinopathy (Fig. 23.19B). It is characterized by formation of new, fragile blood vessels (i.e., neovascularization) at the disk and elsewhere in the retina. These vessels grow in front of the retina along the posterior surface of the vitreous or into the vitreous. They threaten vision in two ways. First, because they are abnormal, they often bleed easily, leaking blood into the vitreous cavity and decreasing visual acuity. Second, the blood vessels attach firmly to the retinal surface and posterior surface of the vitreous, such that normal movement of the vitreous may exert a pull on the retina, causing retinal detachment and progressive blindness. Because early proliferative diabetic retinopathy is likely to be asymptomatic, it must be identified early, before bleeding occurs and obscures the view of the fundus or leads to fibrosis and retinal detachment.

The cause of diabetic retinopathy is uncertain. Several biochemical mechanisms have been proposed as explanations for the development and progression of diabetic retinopathy and have led to exploration of possible treatments. However, except for the demonstration that chronically elevated levels of blood glucose contribute to the development and progression of retinopathy and other complications of diabetes, no mechanism can be regarded as established. Hypertension is also thought to increase the risk for the development and progression of diabetic retinopathy. Recent evidence suggests that the renin–angiotensin system is activated by chronically elevated levels of blood glucose. Angiotensin II increases vascular permeability and promotes angiogenesis, and it has been suggested that a relationship may exist between angiotensin II and vascular endothelial growth factor (VEGF) in ocular tissues. Accordingly, angiotensin-converting enzyme inhibitors or receptor blockers may be useful agents for preventing the progression of diabetic retinopathy. In addition to chronic hyperglycemia and hypertension, several studies have indicated the association of diabetic exudative retinopathy with hypercholesteremia and combined inflammatory mediators on the retinal microvasculature.

Preventing diabetic retinopathy from developing or progressing is considered the best approach to preserving vision. Growing evidence suggests that careful control of blood glucose levels in persons with diabetes mellitus may retard the onset and progression of retinopathy. The ACCORD Eye Study Group demonstrated that intensive management of persons with type 1 diabetes to maintain blood glucose at near-normal levels limited the risk of developing retinopathy. There also is a need for intensive management of hypertension and hyperlipidemia, both of which have been shown to increase the risk of diabetic retinopathy in people with diabetes.

Regular dilated eye examinations are an effective approach to detecting and treating vision-threatening diabetic retinopathy. Current guidelines recommend that people with diabetes have yearly eye examinations, although deviations from this guideline are appropriate in certain low-risk groups. For people with moderate to severe nonproliferative retinopathy, more frequent examinations are often necessary to determine when to initiate treatment. People with any levels of macular edema, severe nonproliferative diabetic retinopathy, or any proliferative retinopathy require the prompt care of an ophthalmologist who is knowledgeable and experienced in the management and treatment of diabetic retinopathy. Women with preexisting diabetes who plan to become pregnant should have a comprehensive eye examination and be counseled about the risk for initiation or progression of diabetic retinopathy. Women with diabetes who become pregnant should have a comprehensive eye examination in the first trimester and close follow-up throughout pregnancy.

Photocoagulation using an argon laser provides the major direct treatment modality for diabetic retinopathy. Treatment strategies include laser photocoagulation applied directly to leaking microaneurysms and grid photocoagulation with a checkerboard pattern of laser burns applied to diffuse areas of leakage and thickening. Because laser photocoagulation destroys the proliferating vessels and the ischemic retina, it reduces the stimulus for further neovascularization. However, photocoagulation of neovascularization near the
Chapter 23  Disorders of Visual Function  599

Studies have shown that signs of hypertensive retinopathy regress with control of blood pressure. There is also evidence that advanced signs of hypertensive retinopathy (e.g., retinal hemorrhages, microaneurysms, and cotton-wool spots) predict stroke and death from stroke independent of elevated blood pressure and other risk factors. Persons with these signs may benefit from close monitoring of cerebrovascular risk and intensive measures to reduce the risk.

**Retinal Detachment**

Retinal detachment involves the separation of the neurosensory retina from the pigment epithelium (Fig. 23.20). It occurs when traction on the inner sensory layer or a tear in this layer allows fluid, usually vitreous, to accumulate between the two layers. There are three types of retinal detachments: exudative, traction, and rhegmatogenous.

*Exudative (or serous) retinal detachment* results from the accumulation of serous or hemorrhagic fluid in the subretinal space due to severe hypertension, inflammation, or neoplastic effusions. It usually resolves with successful treatment of the underlying disease and without visual impairment. *Traction retinal attachment* occurs with mechanical forces on the retina, usually mediated by fibrotic tissue, resulting from previous hemorrhage (e.g., from diabetic retinopathy), injury, infection, or inflammation. Intraocular surgery such as cataract extraction may produce traction on the peripheral retina that causes eventual detachment months or even years after surgery. Correction of traction retinal detachment requires

![Diagram of retinal detachment](image)
disengaging scar tissue from the retinal surface, and vision outcomes are often poor.

Rhegmatogenous detachment (rhegma is the Greek for “rent” or “hole”) is the most common type of retinal detachment. The vitreous is a hydrated gel whose structure is maintained by a collagenous and mucopolysaccharide matrix. As persons age, this macromolecular network begins to liquefy and collapse. As this occurs, the vitreous shrinks and partly separates from the retinal surface, a condition known as posterior vitreous detachment (see Fig. 23.20). Rhegmatogenous detachment occurs when the liquid vitreous enters the subretinal space through the retinal tear. Detachment of the neural retina from the retinal pigment layer separates the receptors from their major blood supply, the choroid. If retinal detachment continues for some time, permanent destruction and blindness of that part of the retina occur.

Etiology and Pathophysiology. Risk factors for retinal detachment include advancing age and myopia. Approximately one in four people between the ages of 61 and 70 years develops a posterior vitreous detachment. In about 10% to 15% of these people, a retinal tear or hole forms as the vitreous pulls away from the retina, especially in the periphery where the retina is thinner.30,37 People with high grades of myopia may have abnormalities in the peripheral retina that predispose to sudden detachment. In moderate to severe myopia or nearsightedness, the axial (anterior-posterior) length of the eye is increased, resulting in an egg-shaped globe. As a result, there is greater vitreoretinal traction, and posterior vitreous detachment may occur at a younger age than in persons without myopia. Also, the retina tends to be thinner and more prone to formation of a hole or tear. Other, less common risk factors include a family history of retinal detachment, a history of congenital eye disease (glaucoma, cataracts), and hereditary vitreopathies with abnormal vitreous gel.

Clinical Manifestations and Diagnosis. The primary symptom of retinal detachment consists of painless changes in vision. Commonly, flashing lights or sparks, followed by small floaters or spots in the field of vision, occur as the vitreous pulls away from the posterior pole of the eye. As detachment progresses, the person perceives a shadow or dark curtain progressing across the visual field. Because the process begins in the periphery and spreads circumferentially and posteriorly, initial visual disturbances may involve only one quadrant of the visual field. Large peripheral detachments may occur without involvement of the macula, so that visual acuity remains unaffected.

Diagnosis is based on a history of visual disturbances (e.g., presence of floaters, luminous rays, or light flashes) and the ophthalmoscopic appearance of the retina. The direct (handheld) ophthalmoscope is useful in detecting an altered red reflex sometimes associated with retinal detachment. However, because the view is narrow, a negative examination with direct ophthalmoscopy cannot exclude the diagnosis of retinal detachment. Ophthalmologists and optometrists use indirect examination techniques that greatly enhance visualization of the peripheral retina.37

Treatment. Because there is a variable interval between a retinal break and retinal detachment, treatment methods focus on early detection and prevention of further vitreous detachment and retinal tear formation. Symptomatic retinal breaks are usually treated with laser or cryotherapy to seal the retinal tears so that the vitreous can no longer leak into the subretinal space. The treatment is more than 95% effective in preventing progression of a retinal tear and preventing retinal detachment.30 The primary treatment of traction retinal detachment is vitreoretinal surgery and may involve vitrectomy, membrane removal, scleral buckling, or pneumatic retinopexy. Scleral buckling is the primary surgical procedure performed to reattach the retina.37 With scleral buckling, a piece of silicone (i.e., the buckle) is sutured and infolded into the sclera, physically indenting the sclera so it contacts the separated pigment and retinal layers. A less invasive procedure, pneumatic retinopexy, involves the intraocular injection of an expandable gas instead of a piece of silicone to form the indentation.

Macular Degeneration

Macular degeneration is characterized by degenerative changes in the central portion of the retina (the macula) that result primarily in loss of central vision (see Fig. 23.1B). Age-related macular degeneration (AMD) is the most common cause of reduced vision in older adults.39 The causes of AMD are poorly understood. In addition to older age, identifiable risk factors include female sex, white race, and cigarette smoking. Increasing evidence suggests that genetic factors may also play a role.36-40 Careful attention should be paid to cardiovascular risk factors, which appear to be more common in people with AMD.

There are two types of AMD: an atrophic nonexudative or “dry” form and an exudative or “wet” form. Although both types are progressive, they differ in terms of manifestations, prognosis, and management. Although many people with AMD manifest nonproliferative changes only, those who experience severe vision loss do so from the development of the exudative form of the disease.

Clinical Manifestations and Diagnosis. Nonexudative AMD is characterized by various degrees of atrophy and degeneration of the outer retina, Bruch membrane, and the choriocapillaris. It does not involve leakage of blood or serum. Therefore, it is called dry age-related macular degeneration (Fig. 23.21). On ophthalmoscopic examination, there are visible changes in the retinal pigment epithelium and pale yellow spots, called drusen, which may occur individually or in groups throughout the macula. Histopathologically, most drusen contain remnants of materials representative of focal detachment of the pigment epithelium. With time, the drusen enlarge, coalesce, and increase in number.
function usually remains intact. With the use of low-vision aids, many of them are able to continue many of their normal activities.

Treatment. Effective therapies for exudative or wet-type macular degeneration include thermal laser photocoagulation, photodynamic therapy, intravitreal and periocular corticosteroid injections, and intravitreal injections of VEGF inhibitors. The decision about specific therapies must take into account the likelihood of visual recovery, which is greater with smaller, more recent lesions, as well as the risks of the various therapies. Currently there is no established effective treatment for the dry form of macular degeneration, and most current therapies and new investigational treatments are directed at choroidal (or subretinal) neovascularization.40,41

Photodynamic laser therapy, which involves the intravenous injection of a dye that is subsequently activated by retinal laser irradiation to produce selective vascular damage, is indicated when the neovascular membrane is well defined. Conventional photocoagulation of subfoveal neovascular membranes is associated with an inevitable immediate reduction in vision because of associated retinal damage and thus is indicated only for extrafoveal membranes. Various surgical procedures to excise subfoveal neovascular membranes or position the macula away from them continue to be investigated.

The VEGF inhibitors that are administered by intravitreal injection include pegaptanib, ranibizumab, and bevacizumab. Pegaptanib is a VEGF inhibitor for the treatment of slow vision loss in eyes affected by all subtypes of AMD. Ranibizumab is a

The level of associated visual impairment is variable and may be minimal. Most people with macular drusen do not experience significant loss of central vision, and the atrophic changes may stabilize or progress slowly. However, people with the nonexudative form of AMD need to be followed closely because the exudative stage may develop suddenly, at any time. Careful monitoring for metamorphopsia, or distorted vision of straight lines, can aid in the early detection of retinal damage.

The exudative or “wet form” of macular degeneration is characterized by the formation of a choroidal neovascular membrane that separates the pigmented epithelium from the neuroretina. These new blood vessels have weaker walls than normal and are prone to leakage. The leakage of serous or hemorrhagic fluid into the subretinal space causes separation of the pigmented epithelium from the neurosensory retina. Over time, the subretinal hemorrhages organize to form scar tissue, causing death of the underlying retinal tissue and loss of all visual function in the corresponding macular area (see Fig. 23.21). The early stages of subretinal neovascularization may be difficult to detect with an ophthalmoscope. Therefore, there is a need to be alert for recent or sudden changes in central vision, blurred vision, or scotomata in people with evidence of AMD.

Although some subretinal neovascular membranes may regress spontaneously, the natural course of exudative macular degeneration is toward irreversible loss of central vision. People with late-stage disease often find it difficult to see at long distances (e.g., in driving), do close work (e.g., reading), see faces clearly, or distinguish colors. However, they may not be severely incapacitated because the peripheral retinal

FIGURE 23.21 • Funduscopic view of different states of AMD. (A) Early intermediate AMD (white arrow), (B) intermediate AMD, and (C) advanced AMD with fibrosis. (From the National Eye Institute, National Institutes of Health.)
recombinant humanized monoclonal antibody with specificity for VEGF for the treatment of the wet form of AMD. Bevacizumab is approved in the United States as an intravenous infusion for treatment of colorectal cancer. Although bevacizumab has not been approved for ophthalmologic neovascular use, it can be used on an off-label basis. The corticosteroids have an angio-static activity that appears to be independent of their hormone activity. The intravitreal injection of these agents bypasses the blood–ocular barrier, achieving therapeutic levels in the eye while avoiding systemic side effects.40

In addition to currently used and forthcoming treatments, there is interest in the so-called preventative category of treatments. Tobacco smoking is consistently identified as a preventable AMD risk. Therefore, elimination of tobacco smoking should be one the first therapeutic recommendations. Preventative recommendations also include dietary supplementation with antioxidants and minerals such as vitamin E (α-tocopherol), vitamin C (ascorbic acid), zinc, and β-carotene for people at risk for developing macular degeneration and for slowing the progression of AMD in people with the disease.41 Although dietary supplements seems reasonable, more experimental data and randomized clinical trials are needed to support their therapeutic value and their most effective composition in terms of single- or multiple-supplement combinations, as well as dosing of particular supplements.

Retinoblastoma
Retinoblastoma is the most common intraocular malignant neoplasm of children, affecting 1 in 20,000.42 The tumor occurs most frequently in children younger than 2 years of age and may even be found at birth. Retinoblastomas are related to inherited or acquired mutations in the retinoblastoma (Rb) tumor suppressor gene, located on the long arm of chromosome 13. If untreated, almost all children die of intracranial extension and disseminated disease. However, new diagnostic and treatment methods allow for a high rate of cure (93% survival in the United States).42–44

Clinical Manifestations. Leukokoria (i.e., cat’s-eye reflex, white reflex, or white pupil) is the most common presenting sign and is often noticed by the family; light entering the eye commonly reflects a yellowish-white color similar to that of the membranous covering of a cat’s eye (Fig. 23.22). Strabismus (squint) is the second most common sign.43 Red, tearing, and painful eyes are a late sign of the disorder. Limited or poor vision is also a late sign. Most retinoblastomas occur sporadically and are unilateral. Up to 25% of sporadic retinoblastomas and most inherited forms of the disorder are bilateral.

Diagnosis and Treatment. Diagnostic measures for detection of retinoblastoma are usually prompted by abnormal results of an eye examination in the hospital nursery or health care provider’s office. All children with a family history of retinoblastoma should be screened soon after birth. Screening should be repeated every 4 to 6 weeks until 1 year of age and then every 2 to 3 months until 3 years of age.43–45 Congenital cataracts are an important cause of childhood leukokoria and should be ruled out. A definitive diagnosis usually requires ophthalmoscopic examination under general anesthesia by an ophthalmologist to obtain complete visualization of both eyes, which facilitates photographing and mapping of the tumors. CT or MRI scans are used to evaluate the extent of intraocular disease and extraocular spread.

The treatment goals of treatment are primarily to save the child’s life and secondarily to save the eye. Treatment options include laser thermotherapy, cryotherapy, chemotherapy, and enucleation (removal of the eye).46 The choice of treatment is determined by the size of the tumor and its location and extension, as well as the visual potential and age of the child. Up to 45% of children treated with eye-preserving therapy may need subsequent therapy for recurrence of tumor, and up to 10% of children with unilateral tumors will develop a tumor in the contralateral eye.45

IN SUMMARY
The neural retina covers the inner aspect of the posterior two thirds of the eyeball and is continuous with the optic nerve. It contains the neural receptors for vision, and it is here that light energy of different frequencies and intensities is converted to graded local potentials, which then are converted to action potentials and transmitted to visual centers in the brain. The photoreceptors normally shed portions of their outer segments. Cells in the pigment epithelium phagocytize these segments. Failure of phagocytosis, as occurs in one form of retinitis pigmentosa, results in degeneration of the pigment layer and blindness.

The retina receives its blood from two sources: the choriocapillaris, which supplies the pigment layer and the outer portion of the sensory retina adjacent to the choroid, and the branches of the retinal artery, which supply the inner half of the retina. Retinal blood vessels are normally apparent through the ophthalmoscope. Neovascularization involves
the formation of new, fragile blood vessels that leak protein and are likely to bleed. Although the cause of neovascularization is uncertain, research links the process with a VEGF produced by the lining of blood vessels. Hypoxia is a key regulator of VEGF-induced retinal neovascularization.

Disorders of retinal vessels can result from many local and systemic disorders, including diabetes mellitus and hypertension. They cause vision loss through changes that result in hemorrhage, production of opacities, and separation of the pigment epithelium and sensory retina. Retinal detachment involves separation of the sensory receptors from their blood supply; it causes blindness unless reattachment is accomplished promptly. Macular degeneration is characterized by loss of central vision due to destructive changes of the macula of the retina. There are two types of AMD: a nonexudative “dry form” that causes atrophy and degeneration of the outer retina and an exudative “wet form” that results in formation of a choroidal neovascular membrane with vessels that leak blood and serum and predispose to separation of the pigmented epithelium from the neuroretina. Although there are currently no effective therapies for the dry form of AMD, effective forms of treatment for the wet form include photodynamic therapy, laser photocoagulation, and intravitreal injection of corticosteroids and VEGF inhibitors.

Retinoblastoma is an intraocular malignant neoplasm of children (most often those younger than 2 years of age) that is caused by inherited or acquired mutations in the retinoblastoma (Rb) tumor suppressor gene. The most common presenting sign is leukokoria (white reflex or white pupil), with strabismus being the second most common sign. With new diagnostic and treatment methods, nearly 95% of retinoblastomas are cured in the United States.

Full visual function requires the normally developed brain-related functions of photoreception and the pupillary reflex. These functions depend on the integrity of all optic pathways, including retinal circuitry and the pathway from the optic nerve to the visual cortex and other visual regions of the brain and brain stem.

**Optic Pathways**

Visual information is carried to the brain by axons of the retinal ganglion cells, which form the optic nerve. Surrounded by pia mater, cerebrospinal fluid, arachnoid, and the dura mater, the optic nerve represents an outgrowth of the brain rather than a peripheral nerve. The optic nerve extends from the back of the optic globe through the orbit and the optic foramen, into the middle cranial fossa, and on to the optic chiasm at the base of the brain (Fig. 23.23). Axons from the nasal portion of the retina remain medial, and those from the temporal retina remain lateral in the optic nerve.

**FIGURE 23.23** • Diagram of optic pathways. The red lines indicate the right visual field and the blue lines the left visual field. Note the crossing of fibers from the medial half of each retina at the optic chiasm. Lesion 1 (right optic nerve) produces unilateral blindness. Lesion 2 (optic chiasm) may involve only those fibers that originate in the nasal half of each retina and cross to the opposite side in the optic chiasm; visual loss involves the temporal half of each field (bitemporal hemianopia). Lesion 3 (right optic tract) interrupts fibers (and vision) originating on the same side of both eyes (homonymous) with loss of vision from half of each field (hemianopia).
The two optic nerves meet and fuse in the optic chiasm, beyond which they are continued as the optic tracts. In the optic chiasm, axons from the nasal retina of each eye cross to the opposite side and join with the axons of the temporal retina of the contralateral eye to form the optic tracts. Thus, one optic tract contains fibers from both eyes that transmit information from the same visual hemifield (half-field.)

**Visual Cortex**

The primary visual cortex (area 17) surrounds the calcarine fissure, which lies in the occipital lobe. It is at this level that visual sensation is first experienced (Fig. 23.24). Immediately surrounding area 17 are the visual association cortices (areas 18 and 19) and several other association cortices. These association cortices, with their thalamic nuclei, must be functional to add meaningfulness to visual perception.

Circuitry in the primary visual cortex and the visual association areas is extremely discrete with respect to the location of retinal stimulation. For example, specific neurons respond to the particular orientation of a moving edge, specific colors, or familiar shapes. This elaborate organization of the visual cortex, with its functionally separate and multiple representations of the same visual field, provides the major basis for visual sensation and perception. Because of this discrete circuitry, lesions of the visual cortex must be large to be detected clinically.

**Visual Fields**

The visual field refers to the area that is visible during fixation of vision in one direction. Because visual system deficits are often expressed as visual field deficits rather than as direct measures of neural function, the terminology for normal and abnormal visual characteristics usually is based on visual field orientation.

Most of the visual field is binocular, or seen by both eyes. This binocular field is subdivided into central and peripheral portions. Central portions of the retina provide high visual acuity and correspond to the field focused on the central fovea; the peripheral and surrounding portion provides the capacity to detect objects, particularly moving objects. Beyond the visual field shared by both eyes, the left lateral periphery of the visual field is seen exclusively by the left nasal retina, and the right peripheral field is seen by the right nasal retina.

As with a camera, the simple lens system of the eye inverts the image of the external world on each retina. In addition, the right and left sides of the visual field also are reversed. The right binocular visual field is seen by the left retinal halves of each eye—the nasal half of the right eye and the temporal half of the left eye.

Once the level of the retina is reached, the nervous system plays a consistent role. The upper half of the visual field is received by the lower half of the retinas of both eyes. Representations of this upper half of the field are carried in the lower half of each optic nerve: They synapse in the lower half of the lateral geniculate nucleus (LGN) of each side of the brain (see Fig. 23.19). Neurons in this part of the LGN send their axons through the inferior half of the optic radiation, looping into the temporal lobe to terminate in the lower half of the primary visual cortex on each side of the brain.

Because of the lateral separation of the two eyes, each eye contributes a different image of the world to the visual field. This is called binocular disparity. Disparity between the laterally displaced images seen by the two eyes provides a powerful source of three-dimensional depth perception for objects within a distance of 30 m. Beyond that distance, binocular disparity becomes insignificant: Depth perception is based on other cues (e.g., the superimposition of the image of near objects over that of far objects and the faster movement of near objects than of far objects).

**Visual Field Defects**

Visual field defects result from damage to the retina, optic pathways, or the visual cortex. Perimetry or visual field testing, in which the limits of the visual field of each eye are measured and plotted in an arc, is used to identify defects and determine the location of lesions.

**Retinal Defects.** All of us possess a hole, or scotoma, in our visual field, of which we are unaware. Because the optic disk, where the optic nerve fibers exit the retina, does not contain photoreceptors, the corresponding location in the visual field constitutes a blind spot approximately 15 degrees temporal to fixation of each eye. Local retinal damage caused by small vascular lesions and other localized pathologic processes can produce additional blind spots. As with the normal blind spot, persons are usually not aware of the existence of scotomata in their visual field unless they encounter problems seeing objects in certain restricted parts of the visual field.

Absences near or in the center of the bilateral visual field can be annoying and even disastrous. Although the hole is not recognized as such, the person finds that a part of a printed page appears or disappears, depending on where the fixation...
point is held. Most people learn to position their eyes to use the remaining central foveal vision for high-acuity tasks. Defects in the peripheral visual field, including the monocular peripheral fields, are less annoying but potentially more dangerous. People who are unaware of the defect, when walking or driving an automobile, do not see cars or bicyclists until their image reaches the functional visual field. This is sometimes too late to avert an accident. Once these people become aware of the defect, they can learn to shift their gaze constantly to obtain visual coverage of important parts of the visual field. If the damage is at the retinal or optic nerve level, only the monocular field of the damaged eye becomes a problem. A lesion affecting the central foveal vision of one eye can result in complaints of eyestrain during reading and other close work because only one eye is being used.

**Disorders of the Optic Pathways**

Localized damage to the optic tracts, LGN, optic radiation, or primary visual cortex affects corresponding parts of the visual fields of both eyes (see Fig. 23.19). Examination of visual system function is of particular importance because lesions at various points along the pathway have characteristic symptoms that assist in the localization of the lesion.

Among the disorders that can interrupt the optic pathway are vascular lesions, trauma, and tumors. For example, normal visual system function depends on adequate perfusion of the ophthalmic artery and its branches; the central artery of the retina; the anterior and middle cerebral arteries, which supply the intracranial optic nerve, chiasm, and optic tracts; and the posterior cerebral artery, which supplies the LGN, optic radiation, and visual cortex. The adequacy of posterior cerebral artery function depends on that of the vertebral and basilar arteries that supply the brain stem. Vascular insufficiency in any one of these arterial systems can seriously affect vision.

Visual field defects of each eye and of the two eyes together are useful in localizing lesions affecting the system. Blindness in one eye is called anopia. If half of the visual field for one eye is lost, the defect is called hemianopia, and if a quarter of the field is lost, it is called quadrantanopia. Enlarging pituitary tumors can produce longitudinal damage through the optic chiasm with loss of the medial fibers of the optic nerve representing both nasal retinas and both temporal visual half-fields. The loss of different half-fields in the two eyes is called a heteronymous loss, and the abnormality is called heteronymous hemianopia. Destruction of one or both lateral halves of the chiasm is common with multiple aneurysms of the circle of Willis. In this condition, the function of one or both temporal retinas is lost, and the nasal fields of one or both eyes are lost. The loss of the temporal fields (nasal retina) of both eyes is called bitemporal heteronymous anopia. With both eyes open, the person with bilateral defects still has the full binocular visual field.

Loss of the optic tract, LGN, full optic radiation, or complete visual cortex on one side results in loss of the corresponding visual half-fields in each eye. Homonymous means “the same” for both eyes. In left-side lesions, the right visual field is lost for each eye and is called complete right homonymous hemianopia. Partial injury to the left optic tract, LGN, or optic radiation can result in the loss of a quarter of the visual field in both eyes. This is called homonymous quadrantanopia, and depending on the lesion, it can involve the upper (superior) or lower (inferior) fields. Because the optic radiation fibers for the superior quarter of the visual field traverse the temporal lobe, superior quadrantanopia is more common.

**Disorders of the Visual Cortex**

Discrete damage to the binocular portion of the primary visual cortex also can result in scotomata in the corresponding visual fields. The central high-acuity portion of the visual field is located at the occipital pole. If the visual loss is in the central high-acuity part of the field, severe loss of visual acuity and pattern discrimination occurs. Mechanical trauma to the cortex results in firing of neurons, experienced as flashes of light or “seeing stars.” Destruction of the polar visual cortex causes severe loss of visual acuity and pattern discrimination. Such damage is permanent and cannot be corrected with lenses.

The bilateral loss of the entire primary visual cortex, called cortical blindness, eliminates all visual experience. Crude analysis of visual stimulation at reflex levels, such as eye-orienting and head-orienting responses to bright moving lights, pupillary reflexes, and blinking at sudden bright lights, may be retained even though vision has been lost. Extensive damage to the visual association cortex (areas 18 and 19) that surrounds an intact primary visual cortex results in a loss of the learned meaningfulness of visual images (i.e., visual agnosia). The person can see the patterns of color, shapes, and movement, but no longer can recognize formerly meaningful stimuli. Familiar objects can be described but not named or reacted to meaningfully. However, if other sensory modalities, such as hearing and touch, can be applied, full recognition occurs. This disorder represents a problem of recognition rather than intellect.

**Testing of Visual Fields**

Crude testing of the binocular visual field and the visual field of each individual eye (i.e., monocular vision) can be accomplished without specialized equipment. In the confrontation method, the examiner stands or sits in front of the person to be tested and instructs the person to focus with one eye closed on the examiner’s nose while random presentations of finger quantities are presented roughly three feet from the observer in each of the four major field quadrants to assess for the awareness of the finger quantities. In a kinetic assessment of the expansiveness of the gross visual field, an object such as a penlight is moved from the center toward the periphery of the person’s visual field and from the periphery toward the center, and the person is instructed to report the presence or absence of the object. By moving the object through the vertical, horizontal, and oblique aspects of the visual field, a crude estimate can be made of the visual field. Large field defects can be estimated by the confrontation method, and it may be the only way for testing young children and uncooperative adults.

Accurate determination of the presence, size, and shape of smaller holes, or scotomata, in the visual field of a particular eye can be demonstrated only by perimetry. This is done by
having the person look with one eye toward a central spot directly in front of the eye while the head is stabilized by a chin rest or bite board. A small dot of light or a colored object is moved back and forth in all areas of the visual field. The person reports whether the stimulus is visible and, if a colored stimulus is used, what the perceived color is. A hemispheric support is used to control and standardize the movement of the test object, and a plot of radial coordinates of the visual field is made. Automated perimetry uses static dots of varying intensity and color, as well as flicker frequency stimuli, to assess higher levels of retinal cell function. Perimetry provides a means of determining alterations from normal and, with repeated testing, a way of following the progress of the condition causing the visual field defect or its treatment.

**IN SUMMARY**

Visual information is carried to the brain by axons of the retinal ganglion cells that form the optic nerve. The two optic nerves meet and fuse in the optic chiasm. The axons of each nasal retina cross in the chiasm and join the uncrossed fibers of the temporal retina of the opposite eye in the optic tract to form the optic tracts. The fibers of each optic tract then synapse in the LGN, and from there, travel by way of the optic radiations to the primary visual cortex in the calcarine area of the occipital lobe. Damage to the visual association cortex can result in the phenomenon of seeing an object without the ability to recognize it (i.e., visual agnosia). Optic pathway or visual cortex damage leads to visual field defects that can be identified through visual field testing. Perimetry, which maps the sensitivity contours of the visual field, can be used to determine the presence, size, and shape of smaller holes, or scotomata, in the visual field of an eye.

For complete visual function, it is necessary that the two eyes focus on the same fixation point, that the image of the object falls simultaneously on the fovea of each eye, and that the retinal and CNS visual mechanisms are functional. It is through these mechanisms that an object is simultaneously imaged on the fovea of both eyes and perceived as a single image. Strabismus and amblyopia are two disorders that affect this highly integrated system.

**Extraocular Eye Muscles and Their Innervation**

Each eyeball can rotate around its vertical axis (lateral or medial rotation in which the pupil moves away from or toward the nose), its horizontal left-to-right axis (vertical elevation or depression, in which the pupil moves up or down), and longitudinal horizontal axis in which the top of the pupil moves toward or away from the nose.

Three pairs of extraocular muscles—the superior and inferior recti, the medial and lateral recti, and the superior and inferior obliques—control the movement of each eye (Fig. 23.25). The four rectus muscles are named according to where they

![Diagram of Extraocular Muscles](image)
The extraocular muscles are innervated by three cranial nerves. The abducens nerve (CN VI) innervates the lateral rectus, the trochlear nerve (CN IV) innervates the superior oblique, and the oculomotor nerve (CN III) innervates the remaining four muscles (Table 23.1). The CN VI (abducens) nucleus, in the caudal pons, innervates the lateral rectus muscle, which rotates the ipsilateral (same side) eye laterally (abduction). Partial or complete damage to this nerve results in weakness or complete paralysis of the muscle. Medial gaze is normal, but the affected eye fails to rotate laterally with an attempted gaze toward the affected side, a condition called medial strabismus. The CN IV (trochlear) nucleus, at the junction of the pons and midbrain, innervates the contralateral or opposite-side superior oblique muscle, which rotates the top of the globe inward toward the nose, a movement called intorsion. In combination with other muscles, it also contributes strength to movement of the innervated eye downward and inward.

The CN III (oculomotor) nucleus, which extends through a considerable part of the midbrain, contains clusters of lower motor neurons for each of the five eye muscles it innervates: inferior rectus, superior rectus, inferior oblique, medial rectus, and levator palpebrae superioris. The medial rectus, superior rectus, and inferior rectus rotate the eye in the directions shown in Table 23.1. The action of the inferior rectus is antagonistic to the superior rectus. Because of its plane of attachment to the globe, the inferior oblique rotates the eye in the frontal plane (i.e., torsion), pulling the top of the eye laterally (i.e., extorsion). CN III also innervates the levator palpebrae superioris muscle that elevates the upper eyelid and is involved in vertical gaze eye movements. As the eyes rotate upward, the upper eyelid is reflexively retracted and in the downward gaze it is lowered, restricting exposure of the conjunctiva to air and reducing the effects of drying.

Communication between the eye muscle nuclei of each side of the brain occurs primarily through the posterior commissure at the rostral end of the midbrain. Longitudinal communication among the three nuclei occurs along a fiber tract called the medial longitudinal fasciculus (MLF), which extends from the midbrain to the upper part of the spinal cord. Each pair of eye muscles is reciprocally innervated, by the MLF or other associated pathways, so that as one muscle contracts, the other relaxes. These MLF-linked communication paths are vulnerable to damage in the caudal midbrain and pons. Damage to the pontine MLF on one side of the brain results in loss of this linkage, such that lateral deviation of the ipsilateral eye is no longer linked to adduction on the contralateral side. If the MLF is damaged bilaterally, the linkage is lost for lateral gaze in either direction.

**Eye Movements and Gaze**

Conjugate movements are those in which the optical axes of the two eyes are kept parallel, sharing the same visual field. Gaze refers to the act of looking steadily in one direction. Eye movements can be categorized into smooth pursuit movements, saccadic movements, optic tremor, and vergence.

*In the schema of the functional roles of the six extraocular muscles, the major directional force applied by each muscle is indicated on the top. These muscles are arranged in functionally opposing pairs per eye and in parallel opposing pairs for conjugate movements of the two eyes. The numbers associated with each muscle indicate the cranial nerve innervation: 3, oculomotor (III) cranial nerve; 4, trochlear (IV) cranial nerve; 6, abducens (VI) cranial nerve.
movements. Although the conjugate reflexes are essential to efficient visual function during head movement or target movement, their circuitry is so deeply embedded in CNS function that they are present and can be elicited when the eyes are closed, during sleep, and in deep coma, and they function normally and accurately in congenitally blind persons.

**Smooth Pursuit Movements.** Smooth pursuit movements are tracking movements that serve to maintain an object at a fixed point in the center of the visual fields of both eyes. The object may be moving with the eyes following, or the object may be stationary with the head moving. Normal eye posture is a conjugate gaze directed straight forward with the head held in a forward-looking posture. Smooth pursuit movements normally begin from this position. In fact, holding a strongly deviated gaze becomes tiring after about 30 seconds, and most people will make head and body rotation adjustments to bring the eyes to a central position within that time.

Asking the person to follow a finger or another object as it is moved slowly through the visual field tests voluntary pursuit movements. Successful conjugate following requires a functional optic system communicating to the superior colliculus and to the primary visual cortex.

**Saccadic Eye Movements.** Saccadic eye movements are sudden, jerky conjugate movements that quickly change the fixation point. During reading, the fixation pattern involves a focus on a word or short series of words and then a sudden jump of the eyes to a new fixation point on the next word or phrase. During the saccade, a person does not experience the blur of the rapidly moving visual field. Saccadic movements are automatic reflex movements that, in most situations, operate at the brain stem level. Saccadic shifts of a gaze toward the source of a sudden, unexpected visual, auditory, tactile, or painful stimulus are a component of the startle pattern. This is functionally a visual grasping reflex, redirecting conjugate gaze in the direction of the startle stimulus.

The frontal eye fields of the premotor cortex are important for voluntary saccadic movements such as reading. If this frontal premotor area is not functional, a person can describe objects in the visual field but cannot voluntarily search the visual environment.

**Eye Tremor.** An eye tremor refers to involuntary, rhythmic, oscillatory eye movements, occurring approximately 10 times per second. Small-range optical tremors are a normal and useful independent function of each eye. One function of the fine optic tremor is to constantly move a bright image onto a new bank of cones, permitting previously stimulated receptors quickly to recover from adaptation.

**Vergence Eye Movements.** Vergence eye movements are those that move the eyes in opposite directions to keep the image of an object precisely positioned on the fovea of each eye. Convergence and divergence, which assist in maintaining a binocularly fixed image in near vision, have a major role in accurate depth perception. The vergence system is driven by retinal disparity (i.e., differential placement of an object’s image on each retina). A nearby target (<30 ft) moving in the same dimension as the optical axis elicits a reflex mechanism that provides redirection of the optical axes of each eye away from parallel (i.e., in opposite directions) in the horizontal plane. This process permits a continued binocular focus on the near target. Perception of depth is a higher-order function of the cortical visual system and is based on one or more of several classes of stimuli, such as superimposition and relative movement.

**Strabismus**

Strabismus, or squint, refers to any abnormality of eye coordination or alignment that results in loss of binocular vision. When images from the same spots in visual space do not fall on corresponding points of the two retinas, diplopia, or double vision, occurs. Strabismus affects approximately 4% of children younger than 6 years of age. Because 30% to 50% of these children sustain permanent secondary loss of vision, or amblyopia, if the condition is left untreated, early diagnosis and treatment are essential.

In standard terminology, the disorders of eye movement are described according to the direction of movement. *Esotropia* refers to medial (inward) deviation, *exotropia* to lateral (outward) deviation, *hypertropia* to upward deviation, *hypotropia* to downward deviation, and *cyclotropia* to torsional deviation. The term *concomitance* refers to equal deviation in all directions of gaze. A nonconcomitant strabismus is one that varies with the direction of gaze. Strabismus may be divided into nonparalytic (concomitant) forms, in which there is no primary muscle impairment, and paralytic (nonconcomitant) forms, in which there is weakness or paralysis of one or more of the extraocular muscles. Strabismus is called *intermittent*, or *periodic*, when there are periods in which the eyes are parallel. It is monocular when the same eye always deviates and the opposite eye fixates. Figure 23.26 illustrates abnormalities in eye movement associated with esotropia and exotropia.

**Nonparalytic Strabismus**

Nonparalytic esotropia is the most common type of strabismus. The individual ocular muscles have no obvious defect and the amount of deviation is constant, or relatively constant in the various directions of gaze. With persistent deviation, secondary abnormalities may develop because of overactivity or underactivity of the extraocular muscles in some fields of gaze.

The disorder may be nonaccommodative, accommodative, or a combination of the two. Infantile esotropia is the most common cause of nonaccommodative strabismus. It occurs in the first 6 months of life, with large-angle deviations, in an otherwise developmentally and neurologically normal infant. Eye movements are full, and the child often uses each eye independently to alter fixation (cross-fixation). The cause of the disorder is unclear. Research suggests that idiopathic strabismus may have a genetic basis; siblings often present with similar disorders.

Accommodative strabismus is caused by disorders such as uncorrected hyperopia of a significant degree, in which the
The extraocular muscles or the cranial nerves supplying these muscles. In general, paralytic strabismus in an older child or adult does not produce amblyopia, and binocular vision can be maintained when the strabismus is corrected. Most adult strabismus represents deterioration of childhood strabismus, which can occur even decades after good ocular alignment.

**Treatment**

Treatment of strabismus is directed toward the development of normal visual acuity, correction of the deviation, and superimposition of the retinal images to provide binocular vision. Early and adequate treatment is crucial because a delay in or lack of treatment can lead to amblyopia and permanent loss of vision. In addition to its effects on visual function, strabismus can have an adverse impact on interpersonal relationships, self-image, schoolwork, and participation in extracurricular activities. Children begin to develop negative attitudes toward classmates with strabismus.

**Paralytic Strabismus**

Paralytic strabismus results from paresis (i.e., weakness) or plegia (i.e., paralysis) of one or more of the extraocular muscles. When the normal eye fixates, the affected eye is in the position of primary deviation. In the case of esotropia, there is weakness of one of the lateral rectus muscles, usually due to a disorder of the abducens nerve (CN VI). When the affected eye fixates, the unaffected eye is in a position of secondary deviation. The secondary deviation of the unaffected eye is greater than the primary deviation of the affected eye. This is because the affected eye requires an excess of innervational impulse to maintain fixation; the excess impulses also are distributed to the unaffected eye, causing overaction of its muscles.

Paralytic strabismus is uncommon in children but accounts for nearly all cases of adult strabismus. It can be caused by infiltrative processes (e.g., Graves disease), myasthenia gravis, stroke, and direct optical trauma. The pathway of the oculomotor, trochlear, and abducens nerves through the cavernous sinus and the back of the orbit make them vulnerable to basal skull fracture and tumors of the cavernous sinus or orbit. In infants, paralytic strabismus can be caused by birth injuries affecting the extraocular muscles or the cranial nerves supplying these muscles. In general, paralytic strabismus in an older child or adult does not produce amblyopia, and binocular vision can be maintained when the strabismus is corrected. Most adult strabismus represents deterioration of childhood strabismus, which can occur even decades after good ocular alignment.
Nonsurgical treatment includes glasses, occlusive patching, and eye exercises (i.e., pleoptics). Glasses are often used in the treatment of accommodative esotropia that occurs with hypermetropia (farsightedness). Because accommodation is linked with convergence, focusing drives the eyes inward, producing esotropia. Intermittent esotropia is commonly treated with patching, use of over-minus glasses, and eye exercises. Although no appreciable deviation is present when the child with intermittent strabismus sees near objects, the deviation becomes obvious when the child views distant objects or is fatigued. Patching for 1 to 2 hours daily for several months works by preventing, rather than treating, suppression of an eye. Patching is most effective in infants, and the efficacy is limited in children older than 3 years of age. The use of over-minus glasses stimulates accommodative convergences, which contracts the exotropic drift. Vision therapy involves exercises to stimulate convergence (e.g., focusing on reading-distance targets up to 30 minutes several times a day) and techniques to train the visual system to recognize the suppressed images. Surgical treatment of intermittent esotropia is indicated when conservative methods fail to correct the deviation. Early treatment of children with intermittent esotropia is not as crucial as it is for those for constant deviations requiring several months to reach normal levels.

Another form of treatment involves the injection of botulinum toxin type A (Botox) into the extraocular muscle to produce a dose-dependent paralysis of that extraocular muscle. Paralysis of the muscle shifts the eye into the field of action of the antagonist muscle. During the time the eye is deviated, the paralyzed muscle is stretched, whereas the antagonistic muscle is contracted. Usually two or more injections of the drug are necessary to obtain a lasting effect.

Amblyopia

Amblyopia, sometimes called lazy eye, describes a decrease in visual acuity resulting from abnormal visual development in infancy or early childhood. The vision loss ranges from mild (worse than 20/25) to severe (legal blindness, 20/200 or worse). It is the leading cause of visual impairment, affecting 1% to 4% of the population. With early detection and treatment, most cases of amblyopia are reversible and the most severe forms of the condition can be prevented.

Etiology and Pathophysiology. Normal development of the thalamic and cortical circuitry necessary for binocular visual perception requires simultaneous binocular use of each fovea during a critical period early in life (0 to 5 years). Amblyopia can result from visual deprivation (e.g., cataracts, ptosis) or abnormal binocular interactions (e.g., strabismus, anisometropia) during visual immaturity. In infants with unilateral cataracts that are dense, central, and larger than 2 mm in diameter, this time is before 2 months of age. In conditions causing abnormal binocular interactions, one image is suppressed to provide clearer vision. In esotropia, vision of the deviated eye is suppressed to prevent diplopia. A similar situation exists in anisometropia, in which the refractive indexes of the two eyes are different. Although the eyes are correctly aligned, they are unable to focus together, and the image of one eye is suppressed.

Treatment. The reversibility of amblyopia depends on the maturity of the visual system at the time of onset and the duration of the abnormal experience. Occasionally in strabismus, some people alternate eye fixation and do not experience deep amblyopia or diplopia. With late adolescent or adult onset, this habit pattern must be unlearned after correction. Amblyopia is remarkably responsive to treatment if the treatment is initiated early in life. Thus, all infants and young children should be evaluated for visual conditions that could lead to amblyopia.

The treatment of children with the potential for development of amblyopia must be instituted well before the age of 6 years to avoid the suppression phenomenon. Surgery for congenital cataracts and ptosis should be done early. Severe refractive errors should be corrected. In children with strabismus, the alternate blocking of the vision in one eye and then the other forces the child to use both eyes for form discrimination. The duration of occlusion of vision in the good eye must be short (2 to 5 hours per day) and closely monitored, or deprivation amblyopia can develop in the good eye as well. Although amblyopia is not likely to occur after 8 or 9 years of age, some plasticity in central circuitry is evident even in adulthood. For example, after refractive correction for longstanding astigmatism in adults, visual acuity improves slowly, requiring several months to reach normal levels.

Eye Examination in Infants and Children

Early detection and prompt treatment of ocular disorders in children are important to prevent amblyopia and lifelong visual impairment. The American Academy of Pediatrics in association with the American Association of Certified Orthoptists, American Association of Pediatric Ophthalmology and Strabismus, and American Academy of Ophthalmology recommends that all newborn infants be examined in the nursery for structural abnormalities and have a red reflex test performed to check for abnormalities in the back of the eye (posterior segment) and opacities in the visual axis, such as cataracts or corneal opacity. An infant with an abnormal red reflex requires immediate referral to an eye care specialist. Visual examinations should then be performed on all well-child visits. These should include age-appropriate evaluation of visual acuity, ocular alignment, and ocular media clarity (cataracts, tumors).

Visual assessment of infants and children younger than 3 years of age is accomplished by determining whether each eye can fixate on an object, maintain fixation, and then follow the object in various gaze positions. Failure to perform these maneuvers indicates significant visual impairment. The assessment should be done binocularly and monocularly. If poor fixation is noted binocularly after 3 months of
age, a significant bilateral eye or brain abnormality should be suspected and the child should be referred for further evaluation. Emphasis should be placed on screening for visual acuity as soon as the child is cooperative enough to complete the examination and at least at 6 months, 2 years, and 4 years old. Decreased vision in one eye requires evaluation for ocular deviation or other ocular abnormalities, which may be difficult to discern on screening examination. Strabismus deviations of only a few degrees, too small to be detected by gross inspection, can lead to amblyopia and vision loss.

Every effort should be made to ensure that eye examinations are performed by properly prepared examiners, using appropriate testing conditions, instruments, and techniques. The results of vision assessments and visual acuity measurements, along with instructions for follow-up care, should be clearly communicated to the parents. Parent’s observations are also important. Questions about whether the child’s eyes seem straight or seem to cross or drift, or appear lazy; whether the child’s eyelids droop or one eyelid tends to close; and, in older children, whether the child seems to see well or tends to hold objects close to his or her face when trying to focus can provide helpful information.

**IN SUMMARY**

Binocular vision depends on the extraocular muscles and their innervating cranial nerves to move the eye up and down and rotate it around its optical axis. For full visual function, it is necessary that the two eyes point toward the same fixation point and the two images become fused. Binocular fusion is controlled by ocular reflex mechanisms that adjust the orientation of each eye to produce a single image. The term **conjugate gaze** refers to the use of both eyes to look steadily in one direction. During conjugate eye movements, the optical axes of the two eyes are maintained parallel with each other as the eyes rotate upward, downward, or from side to side in their sockets.

Strabismus refers to abnormalities in the coordination of eye movements, with loss of binocular eye alignment. This inability to focus a visual image on corresponding parts of the two retinas results in diplopia. Esotropia refers to medial deviation, exotropia to lateral deviation, hypertropia to upward deviation, hypotropia to downward deviation, and cyclotropia to torsional deviation. Paralytic strabismus is caused by weakness or paralysis of the extraocular muscles, whereas nonparalytic strabismus results from the inappropriate length or insertion of the extraocular muscles or from accommodation disorders.

Amblyopia (i.e., lazy eye) is a decrease in visual acuity resulting from abnormal visual development in infancy and early childhood. It results from inadequately developed CNS circuitry because of visual deprivation (e.g., cataracts) or abnormal binocular interactions (e.g., strabismus) during visual immaturity.

**REVIEW EXERCISES**

1. The mother of a 3-year-old boy notices that his left eye is red and watering when she picks him up from day care. He keeps rubbing his eye as if it itches. The next morning, however, she notices that both eyes are red, swollen, and watering. Being concerned, she takes him to the pediatrician in the morning and is told that he has “pink eye.” She is told that the infection should go away by itself.
   
   A. What part of the eye is involved?  
   B. What type of conjunctivitis do you think this child has: bacterial, viral, or allergic?  
   C. Why didn’t the pediatrician order an antibiotic?  
   D. Is the condition contagious? What measures should she take to prevent its spread?

2. During a routine eye examination to get new glasses because she had been having difficulty with her distant vision, a 75-year-old woman is told that she is developing cataracts.
   
   A. What type of visual changes occurs as the result of a cataract?  
   B. What can the woman do to prevent the cataracts from getting worse?  
   C. What treatment may she eventually need?

3. A 50-year-old woman is told by her “eye doctor” that her intraocular pressure is slightly elevated and that although there is no evidence of damage to her eyes at this time, she is at risk for developing glaucoma and should have regular eye examinations.
   
   A. Describe the physiologic mechanisms involved in the regulation of intraocular pressure.  
   B. What are the risk factors for developing glaucoma?  
   C. Explain how an increase in intraocular pressure produces its damaging effects.

4. The parents of a newborn infant have been told that their son has congenital cataracts in both eyes and will require cataract surgery to prevent loss of sight.
   
   A. Explain why the infant is at risk for losing his sight if the cataracts are not removed.  
   B. When should this procedure be done to prevent loss of vision?

Sheila Grossman

The ears are paired organs consisting of an external ear and middle ear, which function in capturing, transmitting, and amplifying sound, and an inner ear that contains the receptive organs that are stimulated by sound waves (i.e., hearing) or head position and movement (i.e., vestibular function). Acute otitis media, or inflammation of the middle ear, is a leading cause of primary care visits and the number one reason for antimicrobial prescriptions for children. Hearing loss is one of the most common disabilities experienced by people in the United States, particularly among older adults. It is also a cause of impaired language development in children. Vertigo, a disorder of vestibular function, is also a common cause of disability among older adults. This chapter is divided into two parts: the first focuses on disorders of the ear and auditory function and the second on disorders of the inner ear and vestibular function.

After completing this section of the chapter, you should be able to meet the following objectives:

- Relate the functions of the eustachian tube to the development of middle ear problems, including acute otitis media and otitis media with effusion.
- Describe the disease process associated with otosclerosis and relate it to the progressive conductive hearing loss that occurs.
- Differentiate between conductive, sensorineural, and mixed hearing loss and cite the more common causes of each.

Disorders of the External Ear

The external ear consists of the auricle, which collects sound, and external acoustic meatus or ear canal, which conducts the sound to the tympanic membrane (Fig. 24.1). The auricle, or

613
pinna, is composed of an irregularly shaped plate of elastic cartilage that is covered by thin skin. Its rim is somewhat thicker, and its fleshy earlobe lacks surrounding cartilage. The funnel shape of the auricle concentrates high-frequency sound entering from the lateral–forward direction into the ear canal. This shape also helps to prevent front-to-back confusion of sound sources.

The external acoustic meatus, or ear canal, is S-shaped and spans 2 to 3 cm in adults. In infants and young children, the canal is relatively shorter so that extra care must be taken when inspecting it with an otoscope. A thin layer of skin containing fine hairs, sebaceous glands, and ceruminous glands lines the ear canal. These glands produce cerumen, or earwax, which has certain antimicrobial properties and is thought to serve a protective function.

Branches of the trigeminal nerve (cranial nerve [CN] V) innervate the anterior portion of the auricle and external part of the ear canal. The posterior portions of the auricle and the wall of the ear canal are innervated by auricular branches of the facial (CN VII), glossopharyngeal (CN IX), and vagus (CN X) nerves. Because of the vagal innervation, the insertion of a speculum or an otoscope into the external ear canal can stimulate coughing or vomiting reflexes, particularly in young children.

The tympanic membrane, approximately 1 cm in diameter, is a thin, transparent membrane that separates the external ear from the middle ear. The tympanic membrane is covered with thin skin externally and the mucous membrane of the middle ear internally. The tympanic membrane is attached in a manner that allows it to vibrate freely when audible sound waves enter the external auditory canal. Movements of the membrane are transmitted through the middle ear to the inner ear.

When viewed through an otoscope, the tympanic membrane appears as a shallow, oval cone pointing inward toward its apex, the umbo (Fig. 24.2). Landmarks include the lightened stripe over the handle of the malleus; the umbo at the end of the handle; the pars tensa (tense part), which constitutes most of the drum; a thinner membrane, the pars flaccida (flaccid part); and the small area above the malleus attachment.

![Diagram of the ear](image-url)
A bright light reflected from an otoscope’s illuminator, called the cone of light, radiates anteroinferiorly from the umbo. The tympanic membrane is semitransparent, and a small, whitish cord, which traverses the middle ear from back to front, can be seen just under its upper edge. This is the chorda tympani, a branch of the intermedius component of the facial nerve (CN VII).²

The function of the external ear is disturbed when sound transmission is obstructed by impacted cerumen, inflammation (i.e., otitis externa), or drainage from the external ear (otorrhea).

**Impacted Cerumen**

Cerumen, or earwax, is a protective secretion produced by the sebaceous and ceruminous glands of the skin that lines the ear canal. Although the ear normally is self-cleaning, the cerumen can accumulate and narrow the canal, causing reversible hearing loss.¹

Impacted cerumen usually produces no symptoms unless it hardens and touches the tympanic membrane, or the canal becomes irritated by a buildup of hardened cerumen. Clinical manifestations may include pain, itching, and a sensation of fullness. As the canal becomes completely occluded, a person may experience a feeling of fullness, a conductive hearing loss, and tinnitus (i.e., ringing in the ears). Because the external auditory canal is innervated by the auricular branch of the vagus nerve, coughing or even cardiac deceleration can result from stimulation of the canal by cerumen impaction or removal attempts.³

In most cases, cerumen can be removed by gentle irrigation using a bulb syringe and warm tap water. Warm water is used to avoid inducing a feeling of disequilibrium due to the vestibular caloric response. The ear canal should be dried thoroughly after irrigation to avoid introducing an infection. Irrigation should be avoided in an only-hearing ear or one that is postsurgical, prone to infection, or suspect for perforation of the tympanic membrane since retaining the hearing of the ear is the highest priority. Alternatively, health care professionals may remove cerumen using an otoscope and a metal curette.⁴

Cerumen that has become hardened or impacted can be softened by instillation of a few drops of a ceruminolytic agent available commercially. Typically, these agents are instilled in the affected ear one or two times daily for up to 4 days before irrigation. Overuse should be avoided because this may make the condition worse. Ceruminolytic agents should not be used in ears that may have a perforated tympanic membrane.⁴

**Otitis Externa**

Otitis externa (AOE) is an inflammation of the external ear that can vary in severity from mild allergic dermatitis to severe cellulitis. It can be caused by infectious agents, irritation (e.g., wearing hearing aids or earphones), or allergic reactions. An estimated 2.4 million health care visits were made in 2007 by people with AOE.² Visits to outpatient clinics for AOE between 2003 and 2007 were highest in children between 5 and 9 years of age, followed closely by children in the 10- to 14-year-old bracket.⁵

**Etiology.** Predisposing factors include frequent exposure to moisture in the ear canal (i.e., swimmer’s ear), trauma to the canal caused by cleaning or scratching, and allergies or skin conditions such as psoriasis. The most common bacterial pathogens are gram-negative rods (Pseudomonas aeruginosa, Proteus species) and fungi (Aspergillus) that grow in the presence of excess moisture.³

**Clinical Manifestations and Treatment.** Otitis externa commonly occurs in the summer and is manifested by itching, redness, tenderness, discharge, impaired hearing, and narrowing of the ear canal because of swelling.⁴ Inflammation of the pinna or canal makes movement of the ear painful. There may be watery or purulent drainage and intermittent hearing loss.

Treatment usually includes the use of eardrops containing an appropriate antimicrobial or antifungal agent. For bacterial infections, a corticosteroid may be combined with an antimicrobial to reduce inflammation. Systemic oral agents are rarely needed.⁶ Protection of the ear from additional moisture (i.e., use of ear plugs) and avoidance of trauma from scratching with cotton-tipped applicators and other devices are important. Preventing recurrences is important, particularly in people who swim frequently.

**Disorders of the Middle Ear and Eustachian Tube**

The middle ear, or tympanic cavity, is a small, mucosa-lined cavity in the petrous portion of the temporal bone¹ (Fig. 24.3A). It is bounded laterally by the tympanic membrane and medially by a bony wall with two openings, the superior oval (vestibular) window and the round (cochlear) window. It is connected anteriorly with the nasopharynx by the eustachian tube, also called the pharyngotympanic tube. Posteriorly, it is connected with small air pockets in the temporal bone called mastoid air spaces or cells.

Three tiny bones, the auditory ossicles, are suspended from the roof of the middle ear cavity and connect the tympanic membrane with the oval window. They are connected by synovial joints and are covered with the epithelial lining of the cavity.¹² The malleus (“hammer”) has its handle firmly fixed to the upper portion of the tympanic membrane. The head of the malleus articulates with the incus (“anvil”), which articulates with the stapes (“stirrup”). These are inserted and sealed into the oval window by an annular ligament. Arrangement of the ear ossicles is such that their lever movements transmit vibrations from the tympanic membrane to the oval window and from there to the fluid in the inner ear. Two tissue-covered openings in the medial wall,

Cholesteatoma

Otosclerosis

FIGURE 24.3 • Disorders of the middle ear. (A) Otitis media. Otitis involves inflammation of the tympanic cavity. Infection often enters through the eustachian tube. (B) Cholesteatoma, a cystlike mass of the middle ear that often extends to involve the temporal bone. (C) Otosclerosis involving formation of new, spongy bone around the stapes and oval window.

the oval and the round windows, provide for the transmission of sound waves between the air-filled middle ear and the fluid-filled inner ear. It is the piston-like action of the stapes footplate that sets up compression waves in the inner ear fluid.

KEY POINTS

DISORDERS OF THE MIDDLE EAR

- The middle ear is a small, air-filled compartment in the temporal bone. It is separated from the outer ear by the tympanic membrane; communication between the nasopharynx and the middle ear occurs through the eustachian tube; and tiny bony ossicles that span the middle ear transmit sound to the sensory receptors in the inner ear.
- Otitis media (OM) refers to inflammation of the middle ear. It can represent an acute otitis media (AOM) that has an abrupt onset and is usually related to bacterial infection or otitis media with effusion (OME) that is associated with fluid in the middle ear without the manifestations of infection and that does not usually require treatment with antimicrobial agents.

Eustachian Tube Dysfunction

The eustachian tube, which connects the nasopharynx with the middle ear, is located in a gap in the bone between the anterior and medial walls of the middle ear (see Fig. 24.1). The eustachian tube serves three basic functions:

1. Ventilation of the middle ear, along with equalization of middle ear and ambient pressures
2. Protection of the middle ear from unwanted nasopharyngeal sound waves and secretions
3. Drainage of middle ear secretions into the nasopharynx

The nasopharyngeal entrance to the eustachian tube, which usually is closed, is opened by the action of the trigeminal (CN V)–innervated tensor veli palatini muscle. Opening of the eustachian tube, which normally occurs with swallowing and yawning reflexes, provides the mechanism for equalizing the pressure of the middle ear with that of the atmosphere. This equalization ensures that the pressures on both sides of the tympanic membrane are the same, so that sound transmission is not reduced and rupture does not result from sudden changes in external pressure, as occurs during plane travel.

The eustachian tube is lined with a mucous membrane that is continuous with the pharynx and the mastoid air cells. Infections from the nasopharynx can travel from the nasopharynx along the mucous membrane of the eustachian tube to the middle ear, causing AOM. Toward the nasopharynx, the eustachian tube becomes lined by columnar epithelium with mucus-secreting cells. Hypertrophy of the mucus-secreting cells is thought to contribute to the mucoid secretions that develop during certain types of OM.

Abnormalities in eustachian tube function are important factors in the pathogenesis of middle ear infections. There are two important types of eustachian tube dysfunction: abnormal patency and obstruction. The abnormally patent tube...
people with repeated episodes of barotrauma related to free-
loss. Placement of ventilation tubes may be considered for
relief and may be used in cases of acute otalgia and hearing
cal incision in the tympanic membrane) provides immediate
i.e, the attachment of the tensor muscle, producing functional
obstruction of the eustachian tube.

Mechanical obstruction results from internal obstruction
or external compression of the eustachian tube. Ethnic
differences in the structure of the palate may increase the
likelihood of obstruction. The most common internal obstruct-
ion is caused by swelling and secretions resulting from
allergy and viral respiratory infections. External compres-
sion by prominent or enlarged adenoidal tissue surrounding
the opening of the eustachian tube may make drainage less
effective. Tumors also may obstruct drainage. With obstruction,
air in the middle ear is absorbed, causing a negative pressure and the transudation of serous capillary fluid into the middle ear.

Barotrauma

Barotrauma represents injury resulting from the inability to
equalize middle ear with ambient pressure during air travel or,
less commonly, underwater diving. It occurs most often dur-
ing air travel when there is a sudden change in atmospheric
pressure. The pressure in the middle ear parallels atmospheric
pressure. Pressure decreases at high altitudes and increases
at lower altitudes. The problem occurs during rapid airplane
descent, when the negative pressure in the middle ear tends
to cause the eustachian tube to collapse. If air cannot pass
back through the eustachian tube, hearing loss and discomfort
develop.

Barotrauma most often occurs in people who travel
while suffering from an upper respiratory tract infection.
Autoinflation measures such as yawning, swallowing, and
chewing gum facilitate opening of the eustachian tube, which
equalizes air pressure in the middle ear. Intranasal or sys-
temic decongestants may be used to prevent symptoms. Acute
negative middle ear pressure that persists on the ground is
treated with decongestants and attempts at autoinflation.
More severe hearing loss or discomfort may require that the
person consult an otolaryngologist. Myringotomy (i.e., surgi-
cal incision in the tympanic membrane) provides immediate
relief and may be used in cases of acute otalgia and hearing
loss. Placement of ventilation tubes may be considered for
people with repeated episodes of barotrauma related to fre-
quent air travel.

Another cause of middle ear barotrauma is hyperbaric
oxygen therapy (increased atmospheric pressure and partial
oxygen pressure in tissues) used for many people with
multiple disorders.

Otitis Media

OM refers to inflammation of the middle ear without refer-
ence to etiology or pathogenesis (see Fig. 24.3A). AOM is
the most common infection for which antimicrobial agents
are prescribed for children in the United States. As such, the
diagnosis and management of OM has a significant impact on
the health of children as well as adults, the cost of providing
care, and overall use of antimicrobial agents.

Several terms are important in reference to OM. Acute
otitis media (AOM) refers to an acute middle ear infection11
(Fig. 24.4). It usually has an abrupt onset of signs and symp-
toms related to middle ear inflammation and effusion. Otitis
media with effusion refers to the presence of fluid in the mid-
dle ear without signs and symptoms of acute ear infection.7
OME is more common than AOM.7 It can develop spontane-
osly because of poor eustachian tube function, accompany a
viral upper respiratory tract infection, or occur as a prelude or
a sequela to AOM.12 Because OME does not usually require
treatment with antimicrobial agents, it is important to dif-
ferentiate OME from AOM to avoid unnecessary use of anti-
microbial agents.

Risk Factors. Although AOM may occur in any age group,
it is the most frequent primary diagnosis in preschool-age
children and is one of the most frequent reasons for a health
care visit for young children. Infants and young children are
at highest risk for AOM, with peak incidences in their first
year of life and again when they begin school. Risk factors
include premature birth, male gender, ethnicity, family history
of recurrent OM, attendance at day care, and presence of sib-
lings in the household. AOM is more frequent in children with
orofacial abnormalities such as cleft lip and palate.

The most important factor that contributes to AOM is
believed to be a dysfunction of the eustachian tube that allows
reflux of fluid and bacteria into the middle ear space from the

nasopharynx. There are two reasons for the increased risk of AOM in infants and young children:

• The eustachian tube is shorter, more horizontal, and wider in this age group than in older children and adults.
• Infection can spread more easily through the eustachian canal of infants who spend most of their day in the supine position.11

Bottle-fed infants have a higher incidence of AOM than breast-fed infants, probably because they are held in a more horizontal position during feeding, and swallowing while in the horizontal position facilitates the reflux of milk into the middle ear. Breast-feeding also provides for the transfer of protective maternal antibodies to the infant.

Measures to reduce the risk for development of AOM include the intranasal influenza vaccine and the heptavalent pneumococcal conjugate vaccine (PCV7). Due to the use of these vaccines, the American Academy of Pediatrics and the American Academy of Family Physicians have recommended new antimicrobial medication if an antibiotic is necessary.11

Etiology. AOM may be of either bacterial or viral origin. The mucosal lining of the middle ear is continuous with the eustachian tube and nasopharynx, and most middle ear infections enter through the eustachian tube (see Fig. 24.1). Bacteria may replicate in fluid of the middle ear to cause bacterial OM. In addition, respiratory viruses may infect the middle ear mucosa, either alone, leading to viral OM, or in combination with bacteria. Most cases of AOM follow an uncomplicated upper respiratory tract infection that has been present for several days. The most common bacteria in AOM is Haemophilus influenzae, with Streptococcus pneumoniae second.11 Respiratory viruses (or virus-derived ribonucleic acid [RNA]) may also be found in the middle ear exudates of children with AOM, either alone or, more commonly, in association with pathogenic bacteria. There is also evidence that the formation of bacterial biofilms may play a role in the pathogenesis of recurrent AOM that does not respond to antimicrobial therapy.12 Biofilms consist of aggregated bacteria, usually adherent to a surface and surrounded by an extracellular matrix covering that isolates and protects them from antimicrobial agents.

Clinical Manifestations. AOM is characterized by the following key criteria:

• Acute onset of otalgia (or pulling of the ears in an infant)
• Fever (>39°C)
• Hearing loss
• Evidence of middle ear inflammation
• Middle ear effusion (MME)11

Children older than 3 years of age may have rhinorrhea or running nose, vomiting, and diarrhea. In contrast, younger children often have nonspecific signs and symptoms that manifest as ear tugging, irritability, nighttime awakening, and poor feeding. Ear pain usually increases as the effusion accumulates behind the tympanic membrane. Perforation of the tympanic membrane may occur acutely, allowing purulent material from the eustachian tube to drain into the external auditory canal. This may prevent spread of the infection into the temporal bone or intracranial cavity. Healing of the tympanic membrane usually follows resolution of the middle ear infection.

OME is a condition in which the tympanic membrane is intact and there is an accumulation of fluid in the middle ear without signs or symptoms of infection. The duration of the effusion may range from less than 3 weeks to more than 3 months. The similarity between OME and AOM is that hearing loss may be present in both conditions. Many cases of OME resolve spontaneously, but some experience recurrent OME. Persistent middle ear fluid from OME results in decreased motility of the tympanic membrane and serves as a barrier to sound conduction.

Diagnosis. Distinguishing between AOM and OME on clinical grounds is often straightforward, but because each condition may evolve into the other without any clearly differentiating physical findings, any system for distinguishing between them is somewhat arbitrary. Because of the increasing antimicrobial resistance, distinguishing between AOM and OME has become increasingly important.

Both AOM without otorrhea (drainage from the ear) and OME are accompanied by otoscopic signs of MME, namely, the presence of at least two of three tympanic membrane abnormalities:

• White
• Yellow, amber (or occasionally blue) discoloration
• Opacification other than scarring
• Decreased or absent motility

With OME the tympanic membrane is often cloudy with distinct impairment of mobility, and an air-fluid level or bubble may be visible in the middle ear.

A definitive diagnosis of AOM requires the following:

• History of acute onset of signs and symptoms
• The presence of MME
• Signs and symptoms of middle ear inflammation13

Signs of middle ear inflammation include fullness or bulging of the tympanic membrane with or without erythema, limited or absent mobility of the tympanic membrane, a purulent (pus-containing) effusion, and ear pain that interferes with normal activity.13 Unless intense, erythema alone is insufficient to support a diagnosis of AOM because erythema without other abnormalities may result from crying or vascular flushing.

The diagnosis of AOM should be confirmed with pneumatic otoscopy and can be supplemented with tympanometry and acoustic reflectometry. The use of the pneumatic otoscope permits the introduction of air into the ear canal for the purpose
of determining tympanic membrane flexibility. The movement of the tympanic membrane is decreased in some cases of AOM and absent in chronic middle ear infection. The diagnosis of AOM can also be confirmed using tympanometry or acoustic reflectometry. Tympanometry is helpful in detecting effusion in the middle ear or high negative middle ear pressure. Portable tympanometers (resembling an otoscope) and desktop instruments are available. Acoustic reflectometry detects reflected sound waves from the middle ear and provides information on whether an effusion is absent or present. Increased reflected sound correlates with an increased likelihood of effusion. This technique is most useful in children older than 3 months, and its success depends on user technique.

Tympanocentesis (puncture of the tympanic membrane with a needle) may be done to relieve pain from an effusion or to obtain a specimen of middle ear fluid for culture and sensitivity testing. The procedure involves the insertion of a needle through the inferior part of the tympanic membrane and is not commonly used. In selected cases of refractory or recurrent middle ear disease, tympanocentesis can help improve diagnostic accuracy, guide treatment, and avoid unnecessary medical or surgical interventions. In instances where the tympanic membrane has perforated with resultant drainage into the external ear, a specimen can be obtained and microbiologic studies can be done to identify the organism.

Treatment. The treatment of OM focuses on symptom control and management of the underlying pathologic process. A number of options for pain management are available, including the local application of heat and use of analgesic drugs such as acetaminophen, ibuprofen, and naproxen. Myringotomy (incision of the tympanic membrane) can be used for relief of pressure in the child who is in severe pain.

The extensive use of antimicrobial agents contributes to the development of bacterial resistance, and evidence exists for the efficacy and safety of two alternative approaches to routine antibiotic prescription: delayed prescription and watchful waiting. Observation without antimicrobial agents is an option in a child with uncomplicated AOM. These approaches involve waiting for 72 hours to see if symptoms improve before institution of antibiotic therapy. Factors to consider when deciding whether to defer treatment include the child’s age, severity of illness, and certainty of the diagnosis. If observation is recommended, it is essential that the parent or caregiver have ready access to communication, follow-up, and a mechanism for obtaining medication if needed.

Most cases of OME resolve spontaneously within a 3-week to 3-month period. The management options for this duration include observation only, antibiotic therapy, or combination antibiotic and corticosteroid therapy. Referral to an otolaryngologist is indicated if the effusion persists for 4 months or longer. Because there is concern over hearing loss and its effect on learning and speech, a hearing evaluation is recommended when OME persists for 3 months or longer or at any time that language delay, learning problems, or a significant hearing loss is suspected.

Children with recurrent OM should be evaluated to rule out any anatomic variations (e.g., enlarged adenoids), allergies, and immunologic abnormalities. Surgical treatment (e.g., tympanostomy tubes, adenoidectomy) may be indicated if the effusion has persisted for 4 months or longer and is accompanied by persistent hearing loss and other manifestations.

Tympanostomy tube insertion is the preferred initial procedure and does not typically include the removal of adenoids unless the child has additional indications, such as postnasal obstruction from enlarged adenoids. The tubes usually are inserted under general anesthesia. The ears of children with tubes must be kept out of water. The adverse effects of tube placement include the following:

- Recurrent otorrhea
- Persistent perforation
- Scarring
- Atrophy of the tympanic membrane
- Cholesteatoma

Adenoidectomy plus myringotomy (without tube insertion) has been effective in older children. Recent research indicates that prompt insertion of tympanostomy tubes for persistent OME in otherwise healthy children who were younger than 3 years of age did not improve developmental outcomes (e.g., literacy, attention, social skills, and academic achievement) as compared with delayed insertion in children in whom effusion continued unremittingly.

Complications of Otitis Media. The complications of OM include hearing loss, adhesive OM, cholesteatoma, mastoiditis, and intracranial complications such as otologic meningitis.

Hearing loss, which is a common complication of OM, usually is conductive and temporary based on the duration of the effusion. Hearing loss that is associated with fluid collection usually resolves when the effusion clears. Permanent hearing loss may occur as the result of damage to the tympanic membrane or other middle ear structures. Cases of sensorineural hearing loss are rare. Persistent and episodic conductive hearing loss in children may impair their cognitive, linguistic, and emotional development. Children younger than 3 years of age with recurrent OME are at increased risk of impaired language development. Additional studies indicate that before 3 years of age, time spent with MME correlates with decreased cognitive development as measured by standardized inventories. However, the degree and duration of hearing loss required to produce such effects are unknown.

Cholesteatomas are cystlike lesions of the middle ear, usually associated with chronic OM, which can be congenital or acquired (see Fig. 24.3B). These cysts can be small in size or large at approximately 4 cm in diameter. They appear whitish or pearlike in color. Although precise mechanisms involved in their development are unclear, it is proposed that chronic inflammation and perforation of the ear drum with ingrowth of squamous epithelium or metaplasia of the secretory epithelium of the middle are contributing factors. Sometimes the cyst ruptures, enhancing the inflammatory
reaction. These lesions, by progressive enlargement, can erode the ossicles, the labyrinth, the adjacent mastoid bone, and the surrounding soft tissues. Although often thought of as a complication of OM, a cholesteatoma may also occur as a congenital condition. Symptoms commonly include painless drainage from the ear and hearing loss. Treatment involves microsurgical techniques to remove the cholesteatomatous material.

Mastoid tenderness and drainage of exudate through a perforated tympanic membrane can occur. Chronic mastoiditis can develop as the result of chronic middle ear infection. The usefulness of antimicrobial agents for this condition is limited. Mastoid or middle ear surgery, along with other medical treatment, may be indicated. The incidence of mastoiditis has markedly decreased compared with the preantimicrobial era.

Intracranial complications are uncommon since the advent of antimicrobial therapy. Although rare, these complications can develop when the infection spreads through vascular channels or by direct extension. These complications are seen more often with chronic supplicative OM and mastoiditis. They include otogenic meningitis, brain abscess, lateral sinus thrombophlebitis or thrombosis, labyrinthitis, and facial nerve paralysis. Any child who develops persistent headache, tinnitus, stiff neck, or visual or other neurologic symptoms should be investigated for possible intracranial complications.

Otosclerosis

Otosclerosis refers to the formation of new spongy bone around the stapes and oval window, which results in progressive deafness (see Fig. 24.3C). In most cases, the condition is familial and follows an autosomal dominant pattern with variable penetrance. Otosclerosis may begin at any time in life but usually does not appear until after puberty, most frequently between the ages of 20 and 30 years.

Otosclerosis begins with resorption of bone in one or more foci. During active bone resorption, the bone structure appears spongy and softer than normal (i.e., osteospongiosis). The resorbed bone is replaced by an overgrowth of new, hard, sclerotic bone. The process is slowly progressive, involving more areas of the temporal bone, especially in front of and posterior to the stapes footplate. As it invades the footplate, the pathologic bone increasingly immobilizes the stapes, reducing the transmission of sound. Pressure of otosclerotic bone on middle ear structures or the vestibulocochlear nerve (CN VIII) may contribute to the development of tinnitus, sensorineural hearing loss, and vertigo.

The symptoms of otosclerosis involve an insidious hearing loss. Initially, the affected person is unable to hear a whisper or someone speaking at a distance. In the earliest stages, the bone conduction by which the person’s own voice is heard remains relatively unaffected. At this point, the person’s own voice sounds unusually loud, and the sound of chewing becomes intensified. Because of bone conduction, most of these persons can hear fairly well on the telephone, which provides an amplified signal. Many are able to hear better in a noisy environment, probably because the masking effect of background noise causes other persons to speak louder.

The treatment of otosclerosis can be medical or surgical. A carefully selected, well-fitting hearing aid may allow a person with conductive deafness to lead a normal life. Because much of the conductive hearing loss associated with otosclerosis is caused by stapedial fixation, surgical treatment involves stapedectomy with stapedial reconstruction using the patient’s own stapes or a stapedial prosthesis. Evidence supports the use of preoperative sodium fluoride to increase the success of the stapedectomy and to increase hearing ability postoperatively.

Disorders of the Inner Ear

The inner ear contains a labyrinth of intercommunicating channels and the receptors for hearing and position sense. Structurally, it consists of an outer bony labyrinth located in the otic capsule of the petrous part of the temporal bone and an inner membranous labyrinth. The membranous labyrinth lies in the bony labyrinth and consists of a complex system of sacs and ducts (i.e., semicircular ducts). The bony labyrinth, which occupies a space with a diameter less than 1.5 cm, is a series of cavities (the cochlea, vestibule, and semicircular canals) (Fig. 24.5). The receptors for hearing are contained in the cochlea, and those for head position sense are contained in the semicircular ducts, the utricle, and the saccule. The vestibule is the central egg-shaped cavity of the bony labyrinth that lies posterior to the cochlea and anterior to the semicircular canals. It contains the utricle and saccule and parts of the balancing apparatus (vestibular labyrinth). The vestibule features the oval window on its lateral wall, occupied by the base of the stapes.

The cochlea is the shell-shaped part of the bony labyrinth that contains the inner membranous cochlear duct, the part of the inner ear concerned with hearing. The spiral canal of the cochlea, which is shaped like a snail shell, begins at the vestibule and winds around a central core of spongy bone called the modiolus. The modiolus contains canals for blood vessels and for distribution of the cochlear nerve. The cochlea consists of three tubes coiled side by side:

1. The scala vestibuli
2. The scala media
3. The scala tympani

The vestibular membrane, also known as Reissner membrane, separates the scala vestibuli and scala media from each other. The basilar membrane separates the scala tympani from the scala media. On the surface of the basilar membrane lies the spiral organ of Corti, which contains a series of electromechanically sensitive cells, the hair cells. They are the receptive organs that generate nerve impulses in response to sound vibrations.

The endolymph and perilymph are the two types of fluids in the inner ear. The scala vestibuli and scala tympani communicate directly with the subarachnoid space around the brain, so the perilymph is similar to cerebrospinal fluid, whereas the endolymph that fills the scala media is an entirely different fluid that is secreted by the stria vascularis on the outer wall of
the scala media (see Fig. 24.6A). The perilymph that fills the scala vestibuli and scala tympani has a high sodium (Na+) concentration, whereas the endolymph that fills the scala media has a high potassium (K+) content. This is significant since there is a direct-current resting membrane potential of about +80 mV that exists between the endolymph and perilymph, with positivity inside the scala media and negativity outside the scala media. This current, which is called the endolymphatic potential, is generated by the continual secretion of K+ ions into the scala media by Na+/K+-adenosine triphosphatase (ATPase) pumps in the stria vascularis. This current is believed to sensitize the hair cells of the organ of Corti, increasing their ability to respond to the slightest sound. Degeneration of the stria vascularis, which has been called the “battery of the cochlea,” and the resultant decline in the endolymphatic potential, is thought to be one of the causes of hearing loss that occurs with aging.\(^{19}\)
Unlike light, which can be transmitted through a vacuum such as outer space, sound is a pressure disturbance originating from a vibrating object and propagated by the molecules of an elastic medium. Sound waves, which are delivered by the stapes footplate to the perilymph, travel throughout the fluid of the inner ear, including up the scala vestibuli, to the apex of the cochlea (see Fig. 24.6A). The vestibular membrane is thin so the sound vibrations from the scala vestibuli are readily transmitted into the scala media. Therefore, as far as sound conduction is concerned, the scala media and scala vestibuli function as a single chamber.

As the pressure wave descends through the endolymph of the scala media, it sets the entire basilar membrane vibrating. The basilar membrane, which becomes progressively more massive from its base to its distal apex, resonates at higher frequencies near the base and at lower frequencies toward its apex as the fluid pressure wave travels up the cochlear spiral. This “tuned” aspect of the basilar membrane results in increased amplitude of displacement at the resonant locations, responding to a particular sound frequency and greater firing of cochlear neurons innervating this region. This mechanism provides the major basis for the discrimination of sound frequency.

Perched on the basilar membrane and extending along its entire length is an elaborate arrangement of columnar epithelium called the spiral organ of Corti (see Fig. 24.6B). Continuous rows of hair cells separated into inner and outer rows can be found in the columnar arrangement of the spiral organ. The cells have hairlike cilia that protrude through openings in an overlying supporting reticular membrane into the endolymph of the cochlear duct. A gelatinous mass, the tectorial membrane, extends from the medial side of the duct to enclose the cilia of the outer hair cells. The hair cells in the organ of Corti are programmed to respond to deformation of the cochlear duct induced by compression waves moving through the perilymph, which ascend and descend in the surrounding scala vestibuli and scala tympani. Selective destruction of hair cells in a particular segment of the cochlea can lead to hearing loss of particular tones.

**Neural Pathways**

Information flows from the hair cells in the organ of Corti to neurons that have their cell bodies in the cochlear ganglion, which follows a spiral course in the bony modiolus of the cochlear spiral. Afferent fibers from the spiral ganglion (i.e., vestibulocochlear or auditory nerve [CN VIII]) travel to the cochlear nuclei in the caudal pons. Many secondary nerve fibers from the cochlear nuclei pass to the opposite side of the pons. These secondary fibers may project to such cell groups as the trapezoid or the superior olivary nucleus, or rostrally toward the inferior colliculus of the midbrain. Ipsilateral projections and interconnections between the nuclei of the two sides occur throughout the central auditory system. Consequently, impulses from either ear are transmitted through the auditory pathways to both sides of the brain stem.

From the inferior colliculus, the auditory pathway passes to the medial geniculate nucleus of the thalamus, where all the fibers synapse. From the medial geniculate nuclei, the auditory tract spreads through the auditory radiation to the primary auditory cortex (area 41), located mainly in the superior temporal gyrus and insula. This area and its corresponding higher-order thalamic nuclei are required for high-acuity loudness discrimination and precise discrimination of pitch. The auditory association cortex (areas 42 and 22) borders the primary cortex on the superior temporal gyrus. This area and its associated higher-order thalamic nuclei are necessary for auditory gnosis, or the meaningfulness of sound, to occur. Experience and the precise analysis of momentary auditory information are integrated during this process.

**Tinnitus**

Tinnitus (from the Latin tinniere, meaning “to ring”) is the perception of abnormal ear or head noises, not produced by an external stimulus. Although it often is described as “ringing of the ears,” it may also assume a hissing, roaring, buzzing, or humming sound. Tinnitus may be constant, intermittent, and unilateral or bilateral. According to the American Tinnitus Association, one in five Americans have tinnitus, only a portion of whom seek medical care. The condition affects both sexes equally, is most prevalent between 40 and 70 years of age, and occasionally affects children.

Although tinnitus is subjective, for clinical purposes it is subdivided into objective and subjective tinnitus. Objective tinnitus refers to those rare cases in which the sound is detected or potentially detectable by another observer. Typical causes of objective tinnitus include vascular abnormalities or neuromuscular disorders. In some vascular disorders, for example, sounds generated by turbulent blood flow (e.g., arterial bruits or venous hums) are conducted to the auditory system. Vascular disorders typically produce a pulsatile form of tinnitus.

Subjective tinnitus refers to noise perception when there is no noise stimulation of the cochlea. A number of causes and conditions have been associated with subjective tinnitus. Intermittent periods of mild, high-pitched tinnitus lasting for several minutes are common in normal-hearing persons.

**Etiology.** Impacted cerumen is a benign cause of tinnitus, which resolves after the earwax is removed. Medications such as aspirin, aminoglycoside antibiotics, and stimulants such as nicotine and caffeine can cause transient tinnitus. Conditions associated with more persistent tinnitus include noise-induced hearing loss, presbycusis (sensorineural hearing loss that occurs with aging), hypertension, atherosclerosis, head injury, and cochlear or labyrinthine infection or inflammation.

The physiologic mechanism underlying subjective tinnitus is largely unknown. It seems likely that there are several mechanisms, including abnormal firing of auditory receptors, dysfunction of cochlear neurotransmitter function or ionic balance, damage to the auditory nerve, or alterations in central processing of the signal.
Diagnosis and Treatment. Because tinnitus is a symptom, the diagnosis relies heavily on the person’s ability to describe the symptoms that have been impacting their hearing and other aspects of life. A history of medication or stimulant use and dietary factors that may cause tinnitus should be obtained. Tinnitus often accompanies hearing disorders, and tests of auditory function usually are done. Causes of objective tinnitus, such as serious vascular abnormalities, should be ruled out.

Treatment measures include elimination of drugs or other substances, such as caffeine, some cheeses, red wine, and foods containing monosodium glutamate, that are suspected of causing tinnitus. The use of an externally produced sound (i.e., noise generators or tinnitus-masking devices) may be used to mask or inhibit the tinnitus. Medications, including antihistamines, anticonvulsant drugs, calcium channel blockers, benzodiazepines, and antidepressants, have been used for tinnitus alleviation, but most are not effective, and many produce undesirable side effects. For persistent tinnitus, psychological interventions may be needed to help the person deal with the stress and distraction associated with the condition. Tinnitus retraining therapy, which includes directive counseling and extended use of low-noise generators to facilitate auditory adaptation to the tinnitus, has met with considerable success. Surgical intervention (i.e., cochlear nerve section, vascular decompression) is a last resort for people in whom all other interventions have failed and in whom the disorder is disabling.

Disorders of the Central Auditory Pathways

The auditory pathways in the brain involve communication between the two sides of the brain at many levels. As a result, strokes, tumors, abscesses, and other focal abnormalities seldom produce more than a mild reduction in auditory acuity on the side opposite the lesion. For intelligibility of auditory language, lateral dominance becomes important. On the dominant side, usually the left side, the more medial and dorsal portion of the auditory association cortex is of crucial importance. This area is called the Wernicke area, and damage to it is associated with auditory receptive aphasia. People with damage to this area of the brain can speak intelligibly and read normally but are unable to understand the meaning of major aspects of audible speech.

Irritative foci that affect the auditory radiation or the primary auditory cortex can produce roaring or clicking sounds, which appear to come from the auditory environment of the opposite side (i.e., auditory hallucinations). Focal seizures that originate in or near the auditory cortex often are immediately preceded by the perception of ringing or other sounds preceded by a prodrome (i.e., aura). Damage to the auditory association cortex, especially if bilateral, results in deficiencies of sound recognition and memory (i.e., auditory agnosia). If the damage is in the dominant hemisphere, speech recognition can be affected (i.e., sensory or receptive aphasia).

Hearing Loss

Hearing is a specialized sense that provides the ability to perceive vibration of sound waves. Functions of the ear include receiving sound waves, distinguishing their frequency, translating this information into nerve impulses, and transmitting these impulses to the central nervous system (CNS). The compression waves that produce sound have frequency and intensity. Frequency indicates the number of waves per unit time (reported in cycles per second [cps] or hertz [Hz]). The human ear is most sensitive to waves in the frequency range of 1000 to 3000 Hz. Most people cannot hear compression waves that have a frequency higher than 20,000 Hz. Waves of higher frequency are called ultrasonic waves, meaning that they are above the audible range. In the audible frequency range, the subjective experience correlated with sonic frequency is the pitch of a sound. Waves below 20 to 30 Hz are experienced as a rattle or drum beat rather than a tone.

Wave intensity is represented by amplitude or units of sound pressure. Generally, the intensity (in power units or ergs per square centimeter) of a sound is expressed as the ratio of intensities between the sound and a reference value. A 10-fold increase in sound pressure is called a bel, after Alexander Graham Bell. Because this representation is too crude to be of use, the decibel (dB), or 1/10 of a bel, is used.

Nearly 36 million or 17% of Americans have hearing loss. It affects people of all age groups. Two to three of every 1000 children in the United States are born deaf or hard of hearing, and 9 of 10 children who are born deaf are born to parents who can hear. Approximately 18% of people between 45 and 64 years of age; 30% of people between 65 and 74 years of age; and 47% of people over 75 years of age have hearing loss. In addition, about 15% or 26 million Americans experience high-frequency hearing loss due to long-term loud noise exposure.

Hearing loss in general is classified as:

- Mild (26 to 40 dB)
- Moderate (41 to 55 dB)
- Severe (71 to 90 dB)
- Profound (91 dB or greater in adults and 70 dB or greater in children)

The term “hard of hearing” is sometimes used for people who have slight difficulty hearing and is defined as hearing loss greater than 20 to 25 dB in adults and greater than 15 dB in children.

There are many causes of hearing loss or deafness. Age and suddenness of onset provide important clues as to the cause of hearing loss. Most hearing loss fits into the categories of conductive, sensorineural, or mixed deficiencies. Hearing loss may be hereditary or acquired, sudden or progressive, unilateral or bilateral, partial or complete, and reversible or irreversible. Chart 24.1 summarizes common causes of conductive and sensorineural hearing loss.
Conductive Hearing Loss

- External ear conditions
- Impacted earwax or foreign body
- Otitis externa
- Middle ear conditions
- Trauma
- Otitis media (acute and with effusion)
- Otosclerosis
- Tumors

Sensorineural Hearing Loss

- Trauma
- Head injury
- Noise
- CNS infections (e.g., meningitis)
- Degenerative conditions
- Presbycusis

Mixed Conductive and Sensorineural Hearing Loss

- Middle ear conditions
- Barotrauma
- Cholesteatoma
- Otosclerosis
- Temporal bone fracture

Sensorineural Hearing Loss

Sensorineural, or perceptive, hearing loss occurs with disorders that affect the inner ear, auditory nerve, or auditory pathways of the brain. With this type of deafness, sound waves are conducted to the inner ear, but abnormalities of the cochlear apparatus or auditory nerve decrease or distort the transfer of information to the brain. Tinnitus often accompanies cochlear nerve irritation. Abnormal function resulting from damage or malformation of the central auditory pathways and circuitry is included in this category.

Etiology. Sensorineural hearing loss is usually irreversible and occurs most commonly in the higher frequencies. Sensorineural hearing loss may have a genetic cause or may result from intrauterine infections such as maternal rubella or developmental malformations of the inner ear. Genetic hearing loss may result from mutation in a single gene (monogenic) or from a combination of mutations in different genes and environmental factors (multifactorial). It has been estimated that 50% of profound deafness in children has a genetic basis. The inheritance pattern for monogenic hearing loss is autosomal recessive in approximately 75% of cases. Hearing loss may begin before development of speech (prelingual) or after speech development (postlingual). Most prelingual forms are present at birth. Hereditary forms of hearing loss also can be classified as being part of a syndrome in which other abnormalities are present or, as nonsyndromic, in which deafness is the only abnormality.

Sensorineural hearing loss also can result from trauma to the inner ear, tumors that encroach on the inner ear or sensory neurons, vascular disorders with hemorrhage, or thrombosis of vessels that supply the inner ear. Other causes of sensorineural
deafness are infections and drugs. Sudden sensorineural hearing loss represents an abrupt loss of hearing that occurs instantaneously or on awakening. It most commonly is caused by viral infections, circulatory disorders, or rupture of the labyrinth membrane that can occur during tympanotomy.

Environmentally induced deafness can occur through direct exposure to excessively intense sound, as in the workplace or at a concert. This is a particular problem in older adults who were working in noisy environments before the mid-1960s, when there were no laws mandating use of devices for protective hearing. Sustained or repeated exposure to noise pollution at sound intensities greater than 100 to 120 dB can cause corresponding mechanical damage to the organ of Corti. If the damage is severe, permanent sensorineural deafness to the corresponding sound frequencies occurs. Wearing earplugs or ear protection is important under many industrial conditions and for musicians and music listeners exposed to high sound amplification.

A number of infections can cause hearing loss. Deafness or some degree of hearing impairment is the most common serious complication of bacterial meningitis in infants and children. The mechanism causing hearing impairment seems to be a suppurative labyrinthitis or neuritis resulting in the loss of hair cells and damage to the auditory nerve. Untreated suppurative OM also can extend into the inner ear and cause sensorineural hearing loss through the same mechanisms.

Among the neoplasms that impair hearing are acoustic neuromas, which account for approximately 6% of all intracranial tumors. Acoustic neuromas are benign Schwann cell tumors affecting CN VIII. These tumors usually are unilateral and cause hearing loss by compressing the cochlear nerve or interfering with blood supply to the nerve and cochlea. Other neoplasms that can affect hearing include meningiomas and metastatic brain tumors. The temporal bone is a common site of metastases.

Drugs that damage inner ear structures are labeled ototoxic. Vestibular symptoms of ototoxicity include light-headedness, dizziness, and dizziness. If toxicity is severe, cochlear symptoms consisting of tinnitus or hearing loss occur. Hearing loss is sensorineural and may be bilateral or unilateral and transient or permanent. Several classes of drugs have been identified as having ototoxic potential, including the aminoglycosides and some other basic antimicrobial agents, antimalarial drugs, some chemotherapeutic drugs, loop diuretics, and salicylates (e.g., aspirin). The symptoms of drug-induced hearing loss may be transient, as often is the case with salicylates and diuretics, or they may be permanent. The risk of ototoxicity depends on the total dose of the drug and its concentration in the bloodstream. It is increased in people with impaired kidney function and in those previously or currently treated with another potentially ototoxic drug.

**Diagnosis and Treatment**

**Diagnosis.** Diagnosis of hearing loss is aided by obtaining a comprehensive history of associated otologic factors such as otalgia, otorrhea, tinnitus, and self-described hearing difficulties. Additionally a thorough physical examination is needed to assess for otorrhea, impacted cerumen, or injury to the tympanic membrane. Hearing tests including conventional audiometry and high-frequency audiometry are most frequently used to diagnose ototoxicity. Rarely an otoacoustic emissions test is conducted. A history of occupational and noise exposure is important, as is the use of medications with ototoxic potential. Testing for hearing loss includes a number of methods, including a person’s reported ability to hear an observer’s voice, use of a tuning fork to test air and bone conduction, audioscopes, and auditory brain stem evoked responses (ABRs).

Tuning forks are used to differentiate conductive and sensorineural hearing loss. A 512-Hz or higher-frequency tuning fork is used because frequencies below this level elicit a tactile response. The Weber test evaluates conductive hearing loss by lateralization of sound. It is done by placing the lightly vibrating tuning fork on the forehead or vertex of the head. In people with conductive losses, the sound is louder on the side with the hearing loss, but in persons with sensorineural loss, it radiates to the side with the better hearing. The Rinne test compares air and bone conduction. The test is done by alternately placing the tuning fork on the mastoid bone and in front of the ear canal. In conductive losses, bone conduction exceeds air conduction. In sensorineural losses, the opposite occurs.

An audioscope is a rechargeable battery–powered, handheld instrument that combines a pure-tone screening audiometer and otoscope into a single unit. It produces pure sounds at 500, 1000, 2000, and 4000 Hz, at loudness levels of 20, 25, and 40 dB. If a person cannot hear pure tones at 1000 to 2000 Hz (usual speech frequencies), referral for a full audiogram is indicated. The audiogram is an important method of analyzing a person’s hearing and is generally considered the gold standard for diagnosis of hearing loss. It is done by an audiologist and requires highly specialized sound production and control equipment. Pure tones of controlled intensity are delivered, usually to one ear at a time, and the minimum intensity needed for hearing to be experienced is plotted as a function of frequency.

The ABR is a noninvasive method that permits functional evaluation of certain defined parts of the central auditory pathways. Electroencephalographic (EEG) electrodes and high-gain amplifiers are required to produce a record of the electrical wave activity elicited during repeated acoustic stimulations of either or both ears. ABR recording involves subjecting the ear to loud clicks and using a computer to pick up nerve impulses as they are processed in the midbrain. With this method, certain of the early waves that come from discrete portions of the pons and midbrain auditory pathways can be correlated with specific sensorineural abnormalities. Also, magnetic resonance imaging (MRI) and computed tomography (CT) are used to identify lesions.

**Treatment.** Hearing loss can have many consequences. It produces a loss of the important communicative function of auditory language. Social isolation and depressive disorders are common in hearing-impaired elderly. Safety issues, both in and out of the home, may become significant.
Treatment of hearing loss can range from simple removal of impacted cerumen in the external auditory canal to surgical procedures such as those used to reconstruct the tympanic membrane. For other people, hearing aids and cochlear implants are an option. Although many assistive devices are available to people with hearing loss, understanding on the part of family and friends is perhaps the most important. The interpretation of speech involves both visual and auditory clues. It is important that people speaking to people with hearing impairment face the person and articulate so that lip-reading cues can be used.

Hearing aids remain the mainstay of treatment for many people with conductive and sensorineural hearing loss. With microcircuitry, hearing aids are designed with computer chips that allow multiple programs to be placed in a single hearing aid. The various programs allow the user to select a specific setting for different listening situations. The development of microcircuitry has also made it possible for hearing aids to be miniaturized to the point that, in many cases, they can be placed deep in the ear where they take advantage of the normal shape of the external ear and ear canal. Although modern hearing aids have improved greatly, they cannot replicate the hearing person’s ability to hear both soft and loud noises. They also fail to consistently filter out distorted or background noise. Other aids for the hearing impaired include alert and signal devices, assisted-listening devices from telephone companies, and dogs trained to respond to various sounds.

Surgically implantable cochlear prostheses for the profoundly deaf have been successful with adults and children over 1 year old. Approximately 219,000 people worldwide have been treated with a cochlear implant. These prostheses are inserted into the scala tympani of the cochlea and work by providing direct stimulation to the auditory nerve, bypassing the stimulation that typically is provided by transducer cells but that is absent or nonfunctional in a deaf cochlea. For the implant to work, the auditory nerve must be functional. Although early implants used a single electrode, current implants use multielectrode placement, enhancing speech perception. Much of the progress in implant performance has been achieved through improvements in the speech processors that convert sound into electrical stimuli. Advances in the development of the multichannel implant have improved performance such that cochlear implants have been established as an effective option for adults and children with profound hearing impairment. Most people who become deaf after learning speech derive substantial benefit when cochlear implants are used in conjunction with lipreading. Some are able to understand some speech without lipreading, and some are able to communicate by telephone.

Hearing Loss in Infants and Children

Even slight or unilateral hearing loss can impact negatively the young child’s language development. Although estimates vary depending on the group surveyed and testing methods used, 1 to 2 per 1000 newborns have moderate (30 to 50 dB), severe (50 to 70 dB), or profound (≥70 dB) sensorineural hearing loss. An additional 1 to 2 per 1000 may have milder (20 dB) or unilateral impairments. When considering less severe or transient conductive hearing loss that is commonly associated with middle ear disease in young children, the numbers are even greater.

The cause of hearing impairment in children may be conductive or sensorineural. Most conductive hearing loss is caused by middle ear infections. Causes of sensorineural hearing impairment include genetic, infectious, traumatic, and ototoxic factors. Genetic causes are probably responsible for as much as 50% of sensorineural hearing loss in children. The most common infectious cause of congenital sensorineural hearing loss is cytomegalovirus (CMV), which infects 1 of 100 newborns in the United States each year; of these, about 1200 to 2000 have sensorineural hearing loss. Of particular concern is the fact that congenital CMV infection can cause both symptomatic and asymptomatic hearing loss in the newborn. Some children with congenital CMV infection, who were asymptomatic as newborns, have suddenly lost residual hearing at 4 to 5 years of age.

Postnatal causes of sensorineural hearing loss include beta-hemolytic streptococcal sepsis in the newborn and bacterial meningitis. Streptococcus pneumoniae is the most common cause of bacterial meningitis that results in sensorineural hearing loss after the neonatal period. This cause may become less frequent with the routine administration of the conjugate pneumococcal vaccine. Other causes of sensorineural hearing loss are toxins and trauma. Early in pregnancy, the embryo is particularly sensitive to toxic substances, including ototoxic drugs such as the aminoglycosides and loop diuretics. Trauma, particularly head trauma, may cause sensorineural hearing loss.

Hearing impairment can have a major impact on the development of a child. Therefore, early identification through screening programs is strongly advocated. The American Academy of Pediatrics (AAP) and the Joint Commission on Infant Hearing (JCIH) published a position paper calling for universal screening of all infants by physiologic measurements before 1 month of age, with proper intervention no later than 6 months of age. Many states have now enacted legislation supporting the position paper. As a result, newborn hearing screening programs have been implemented in newborn nurseries throughout the United States. The currently recommended screening techniques are either the transient evoked otoacoustic emissions (TEOAEs) or the ABR. Both methodologies are noninvasive, relatively quick (<5 minutes), and easy to perform. The TEOAE measures sound waves generated in the inner ear (cochlea) in response to clicks or tone bursts emitted and recorded by a minute microphone placed in the external ear canals of the infant. The ABR uses three electrodes pasted to the infant’s scalp to measure the EEG waves generated by clicks. Because many children become hearing impaired after the neonatal period and are not identified by neonatal screening programs, the AAP and JCIH recommend that all infants with risk factors for delayed onset of progressive hearing loss receive ongoing audiologic and medical monitoring and at appropriate intervals thereafter.
Hearing Loss in Older Adults

The term presbycusis is used to describe degenerative hearing loss that occurs with advancing age. Age-related hearing loss is the most frequently seen type of hearing disorder. Between 25% and 40% of the population aged 65 years and older is hearing impaired. Because of its high prevalence, presbycusis is a common social and health problem.

The hearing loss associated with presbycusis is typically gradual, bilateral, and characterized by high-frequency hearing loss. It is further characterized by reduced hearing sensitivity and speech understanding in noisy environments, slowed central processing of acoustic information, and impaired localization of sound sources. The disorder first reduces the ability to understand speech and, later, the ability to detect, identify, and localize sounds. The most common complaint of people with presbycusis is not that they cannot hear, but rather that they cannot understand what is being said. For example, they often confuse words like mash with math, map with mat, and Sunday with some day. High-frequency warning sounds, such as beeps, turn signals, and escaping steam, are not heard and localized, with potentially dangerous results.

Although the degeneration with aging of the sensory cells in the cochlea, supporting cells, and cochlear nerve are well described, the cause of presbycusis is largely unknown. Because of the age at which the problems occur varies widely, it seems likely that the disorder results from a mixture of acquired auditory stresses, trauma, and otologic diseases superimposed on an intrinsic, genetically controlled, aging process.

Given the high prevalence of presbycusis in people of retirement age and the adverse effects of hearing loss on well-being, screening for hearing loss should be performed at annual health care visits. The single question “do you have a hearing problem?” is usually an effective method of screening. The 10-item Hearing Handicap Inventory for the Elderly–Screening (HHIE-S) Version is also a widely used screening tool. Clinical measures for hearing loss such as whispered voice tests and finger friction tests are reportedly imprecise and are not reliable methods for screening. Screening audiometry administered by someone trained in its use is a practical and cost-effective method for detecting significant hearing loss. The equipment needed for screening audiometry is lightweight, low cost, and well accepted by persons being tested.

Several otologic abnormalities can be identified and treated. Cerumen impaction may result in substantial hearing loss and can be found in almost one third of older adults with hearing loss. Many older adults are on multiple medications, some of which may possess ototoxic potential. A frequently overlooked ototoxic agent is aspirin. Little is known about what level of dosage causes ototoxicity, but it is generally believed that 81 mg of aspirin on a daily basis is safe. Fortunately, in most cases, the resulting tinnitus and hearing loss are temporary and reversible with cessation of the drug.

The majority of hearing loss in older adults is sensorineural. In mild to severe loss, the most effective treatment is hearing amplification with hearing aids, speech reading, and assistive listening devices (e.g., hearing aids with the telephone, captioning on televised programs, flashing alarms). Cochlear implants are indicated at any age for people with bilateral hearing losses not materially helped by hearing aids.

IN SUMMARY

Hearing is a specialized sense whose external stimulus is the vibration of sound waves. Our ears receive sound waves, distinguish their frequencies, translate this information into nerve impulses, and transmit them to the CNS. Anatomically, the auditory system consists of the outer ear, middle ear, and inner ear, the auditory pathways, and the auditory cortex. The middle ear is a tiny, air-filled cavity in the temporal bone. A connection exists between the middle ear and the nasopharynx. This connection, called the eustachian tube, allows equalization of pressure between the middle ear and the atmosphere. The inner ear contains the receptors for hearing.

Disorders of the auditory system include infections of the external and middle ear, otosclerosis, and conduction and sensorineural deafness. Otitis externa is an inflammatory process of the external ear. OM is an inflammation of the middle ear without reference to etiology or pathogenesis. AOM, which refers to an acute middle ear infection, is one of the most common illnesses in children. It usually follows an upper respiratory tract infection, has an abrupt onset, and is characterized by otalgia, fever, and hearing loss. OME refers to the presence of fluid in the inner ear without signs and symptoms of acute ear infection. The effusion that accompanies OM can persist for weeks or months, interfering with hearing and impairing speech development. It is important to differentiate OME from AOM to avoid unnecessary antimicrobial use. Otosclerosis is a familial disorder of the otic capsule. It causes bone resorption followed by excessive replacement with sclerotic bone. The disorder eventually causes immobilization of the stapes and conduction deafness.

Deafness, or hearing loss, can develop as the result of a number of auditory disorders. It can be conductive, sensorineural, or mixed. Conduction deafness occurs when transmission of sound waves from the external to the inner ear is impaired. Sensorineural deafness can involve cochlear structures of the inner ear or the neural pathways that transmit auditory stimuli. Sensorineural hearing loss can result from genetic or congenital disorders, trauma, infections, vascular disorders, tumors, or ototoxic drugs. Hearing loss in infants and young children impairs language and speech development. In the elderly, hearing loss is a common condition resulting in significant loss of social well-being. Treatment of hearing loss includes the use of hearing aids and, in some cases of profound deafness, implantation of cochlear prosthesis.
KEY POINTS

DISORDERS OF THE VESTIBULAR SYSTEM

- The vestibular system has extensive interconnections with neural pathways controlling vision, hearing, and autonomic nervous system function. Disorders of the vestibular system are characterized by vertigo, nystagmus, tinnitus, nausea and vomiting, and autonomic nervous system manifestations.
- Disorders of vestibular function can result from repeated stimulation of the vestibular system such as during car, air, and boat travel (motion sickness); acute infection of the vestibular pathways (acute vestibular neuritis); dislodgement of otoliths that participate in the receptor function of the vestibular system (benign paroxysmal positional vertigo [BPPV]); or distention of the endolymphatic compartment of the inner ear (Ménière disease).

The Vestibular System and Vestibular Reflexes

The vestibular receptive organs, which are located in the inner ear, and their connections to the CNS contribute to the reflex activity necessary for effective posture and movement in a physical world governed by momentum and gravitational field. Because the vestibular apparatus is part of the inner ear and located in the head, it is head position and acceleration that is sensed. The vestibular system serves two general and related functions. It maintains and assists recovery of stable body and head position through control of postural reflexes, and it maintains a stable visual field despite marked changes in head position.

Peripheral Vestibular Apparatus

The peripheral apparatus of the vestibular system is contained in the bony labyrinth of the inner ear next to and continuous with the cochlea of the auditory system. Like the cochlea, it consists of two fluid-filled compartments—an outer bony labyrinth that is filled with perilymph and an inner membranous labyrinth that is filled with endolymph. The bony labyrinth is divided into three semicircular canals and

DISORDERS OF VESTIBULAR FUNCTION

After completing this section of the chapter, you should be able to meet the following objectives:

- Explain the function of the vestibular system with respect to postural reflexes and maintaining a stable visual field despite marked changes in head position.
- Compare the manifestations and pathologic processes associated with benign paroxysmal positional vertigo and Ménière disease.
- Differentiate the manifestations of peripheral and central vestibular disorders.

The Vestibular System

The vestibular system, which is a part of the inner ear, is responsible for maintaining balance and position. It consists of two main components: the peripheral vestibular apparatus and the central vestibular apparatus. The peripheral apparatus includes the utricle, saccule, and three semicircular canals, each of which contains hair cells that are sensitive to linear and angular acceleration, respectively.

The central vestibular apparatus is located in the brainstem and cerebellum and is responsible for processing and integrating vestibular information with visual and somatosensory inputs to maintain balance and posture. The vestibulo-ocular reflex (VOR) is a key example of how the vestibular system contributes to maintaining visual stability and preventing retinal image slip during head movements.

Central Vestibular Apparatus

The central vestibular apparatus includes the vestibular nuclei in the medulla and pons and the cerebellum. These structures receive input from the peripheral vestibular apparatus and process this information to generate appropriate motor commands for maintaining balance and posture. The cerebellum, in particular, is crucial for coordinating eye and head movements to maintain visual stability during head movements.

The vestibular nuclei are connected to various motor nuclei in the brainstem and spinal cord, allowing for the generation of eye movements and postural adjustments. Lesions in the central vestibular apparatus can lead to symptoms such as dizziness, unsteadiness, and oscillopsia (a sensation of visual instability).

The vestibular system plays a critical role in maintaining balance and posture, and disruptions in this system can lead to a variety of symptoms. Proper assessment and treatment of vestibular disorders are essential to maintaining optimal function and quality of life.
a central vestibule or egg-shaped cavity that lies posterior to
the cochlea and anterior to the semicircular canals. Suspended
in the perilymph and united by a duct are two membranous
labyrinth sacs, the saccule and utricle. The smaller saccule is
continuous with the membranous labyrinth extending ante-
riorly into the cochlea through the ductus reuniens, which
connects with the cochlear duct. The utricle is continuous with
the ducts extending into the semicircular canals posteriorly. The
receptors of the vestibular system consist of small patches of
hair cells located in membranous ampullae of three semicircu-
lar ducts and the maculae of the saccule and utricle.9

The cavities of the three semicircular canals, the lateral,
anterio, and posterior canals, are oriented in one of three
planes of space. The lateral (horizontal) canals are in the same
plane, whereas the anterior (superior) canal of one side is par-
allel with the posterior (inferior) canal on the other side, and
the two function as a pair. Located in each semicircular canal
is a corresponding semicircular duct, which communicates
with the utricle. Each of these ducts has an enlarged swelling
at one end called an ampulla (see Fig. 24.7A). The ampulla of
each of the semicircular canals contains a ridge that is covered
by a sensory epithelium with hair cells that are raised into a
crest, called the crista ampullaris, which lies at a right angle
to the duct (Fig. 24.7B). These hair cells are innervated by the
primary afferents of the vestibular nerve, which is a subdivi-
sion of the eighth CN.

The hair cells of the crista ampullaris extend into a flexi-
ble gelatious mass, called the cupula, which essentially closes
off fluid flow through the semicircular ducts (see Fig. 24.7C).
When the head begins to rotate around the axis of a semicir-
cular canal (i.e., undergoes angular acceleration), the momen-
tum of the endolymph causes an increase in pressure on one
side of the cupula. This is similar to the lagging behind of
the water in a glass that is suddenly rotated, except that the
endolymph cannot flow past the cupula. Instead, the endo-
lymph applies a differential pressure to the two sides of the
cupula, bending the hair bundles. Because all the hair cells in
each semicircular canal share a common orientation, angular
acceleration in one direction increases afferent nerve activ-
ity, whereas acceleration in the opposite direction diminishes
nerve activity. Impulses from the semicircular ducts are par-
icularly important in reflex movement of the eyes. Vestibular
nystagmus is a complex phenomenon that occurs during and
immediately after rotational motion.40 As you rotate your
head, your eyes slowly drift in the opposite direction and then
jump rapidly back toward the direction of rotation to establish
a new fixation point.

Both the saccule and utricle have equilibrium receptors
called a macula that relate to changes in head position. Each
macula is a small, flat epithelial patch containing supporting
cells and sensory hair cells, the sides and bases of which syn-
apse with sensory endings of the vestibular nerve (Fig. 24.8).
Each group of hair cells has a number of small cilia called ste-
reo cilia, plus one large cilium, the kinocilium. The kinocilium
is located at one side of the cell, and the stereocilia become
progressively shorter toward the other side of the cell. Minute
filamentous attachments connect the tip of each stereocilium
to the next longer stereocilium and finally to the kinocilium.
Movement of the head in one direction causes movement of
the adjoined stereocilia and kinocilium and depolarization or
activation of the receptor and movement of the head in the
other direction causes hyperpolarization or inactivation of the
receptor.

The hair cells in both the utricular and saccular macula-
lae are embedded in a flattened gelatious mass, the otolithic
membrane, which is studded with tiny stones (calcium car-
bonate crystals) called otoliths. Although they are small, the
density of the otoliths increases the membrane’s weight and
its resistance to change in motion. When the head is tilted,
the gelatious mass shifts its position because of the pull of the
gravitational field, bending the stereocilia of the macular
hair cells. Although each hair cell becomes more or less excit-

![FIGURE 24.8](image_url)
able depending on the direction in which the cilia are bending, the hair cells are oriented in all directions, making these sense organs sensitive to static or changing head position in relation to the gravitational field. In a condition called benign paroxysmal positional vertigo (BPPV, a sensation of whirling or spinning motion), the otoliths become dislodged from their gelatinous base, causing a vertigo that is precipitated by changes in the recumbent head position.

**Neural Pathways**

The response to body imbalance, such as stumbling, must be fast and reflexive. Hence, information from the vestibular system goes directly to reflex centers in the brain stem, rather than to the cerebral cortex. Ganglionic cells, homologous with dorsal root ganglion cells, form afferent ganglia: the superior and inferior vestibular ganglia that innervate the hair cells of the peripheral vestibular apparatus. The central axons of these ganglion cells become the superior and inferior vestibular nerves, which become part of the vestibulocochlear nerve (CN VIII).

Impulses from the vestibular nerves initially pass to one of two destinations: the vestibular nuclear complex in the brain stem or the cerebellum. The vestibular nuclei, which form the main integrative center for balance, also receive input from visual and somatic receptors, particularly from proprioceptors in the neck muscles that report the angle or inclination of the head. The vestibular nuclei integrate this information and then send impulses to the brain stem centers that control the extrinsic eye movements (CN III, IV, and VI) and reflex movements of the neck, limb, and trunk muscles (through the vestibulospinal tracts). These reflexes include the vestibuloocular reflexes that keep the eyes still as the head moves and the vestibulospinal reflexes that enable the musculoskeletal system to make the quick adjustments needed to maintain or regain balance.

Neurons of the vestibular nuclei also project to the thalamus, the temporal cortex, the somesthetic area of the parietal cortex, and the chemoreceptor trigger zone. The thalamic and cortical projections provide the basis for the subjective experiences of position in space and of rotation. Connections with the chemoreceptor trigger zone stimulate the vomiting center in the brain. This is thought to account for the nausea and vomiting that accompany vestibular disorders.

**Nystagmus**

The term nystagmus refers to the involuntary rhythmic and oscillatory eye movements that preserve eye fixation on stable objects in the visual field during angular and rotational movements of the head. The vestibuloocular reflexes produce slow compensatory conjugate eye rotations that occur in the direction precisely opposite to ongoing head rotation and provide for continuous, ongoing reflex stabilization of the binocular fixation point. This reflex can be demonstrated by holding a pencil vertically in front of the eyes and moving it from side to side through a 10-degree arc at a rate of approximately five times per second. At this rate of motion, the pencil appears blurred because a different and more complex reflex, smooth pursuit, cannot compensate quickly enough. However, if the pencil is maintained in a stable position and the head is moved back and forth at the same rate, the image of the pencil is clearly defined. The eye movements are the same in both cases. The reason that the pencil image remains clear in the second situation is because the vestibuloocular reflexes keep the image of the pencil on the retinal fovea. When compensatory vestibuloocular reflexes carry the conjugate eye rotations to their physical limit, a very rapid conjugate movement moves the eyes in the direction of head rotation to a new fixation point, followed by a slow vestibuloocular reflex as the head continues to rotate past the new fixation point. This pattern of slow–fast–slow movements is called nystagmus. Clinically, the direction of nystagmus is named for the fast phase of nystagmus.

Nystagmus can be classified according to the direction of eye movement: horizontal, vertical, rotary (torsional), or mixed. If head rotation is continued, friction between endolymph and semicircular duct walls results in endolymph rotating at the same velocity as the head, and nystagmus adapts to a stable eye posture. If rotation is suddenly stopped, vestibular nystagmus reappears in the direction precisely opposite to the angular accelerating nystagmus. This results because the inertia of the endolymph is again bending ampullary hair cells of a now stationary ampulla.

Spontaneous nystagmus that occurs without head movement or visual stimuli is always pathologic. It seems to appear more readily and more severely with fatigue and to some extent can be influenced by psychological factors. Nystagmus due to a CNS pathologic process, in contrast to vestibular end organ or vestibulocochlear nerve sources, seldom is accompanied by vertigo. If present, the vertigo is mild. Nystagmus eye movements can be tested by caloric stimulation or rotation.

**Vertigo**

Disorders of vestibular function are characterized by a condition called vertigo, in which an illusion of motion occurs. With vertigo, the person may be stationary and the environment in motion (i.e., objective vertigo), or the person may be in motion and the environment stationary (i.e., subjective vertigo). Persons with vertigo frequently describe a sensation of spinning, “to-and-fro” motion, or falling. Vertigo is different than light-headedness, faintness, or syncope (Table 24.1). It is considered more of a spinning of oneself or the surroundings. Presyncope, which is characterized by a feeling of light-headedness or “blacking out,” is commonly caused by postural hypotension or a stenotic lesion in the cerebral circulation that limits blood flow. An inability to maintain normal gait may be described as dizziness despite the absence of objective vertigo. The unstable gait may be caused by disorders of sensory input (e.g., proprioception), peripheral neuropathy, gait problems, or disorders other than vestibular function and usually is corrected by touching a stationary object such as a wall or table.
Vertigo or dizziness can result from central or peripheral vestibular disorders. Approximately 85% of people with vertigo have a peripheral vestibular disorder, whereas only 15% have a central disorder. Vertigo due to peripheral vestibular disorders tends to be severe in intensity and episodic or brief in duration. In contrast, vertigo due to central vestibular causes tends to be mild and constant and chronic in duration.

Motion Sickness

Motion sickness is a form of normal physiologic vertigo. It is caused by repeated rhythmic stimulation of the vestibular system, such as that encountered in car, air, or boat travel. Vertigo, malaise, nausea, and vomiting are the principal symptoms. Autonomic signs, including lowered blood pressure, tachycardia, and excessive sweating, may occur. Hyperventilation, which commonly accompanies motion sickness, produces changes in blood volume and pooling of blood in the lower extremities, leading to postural hypotension and sometimes to syncope. Some persons experience a variant of motion sickness, complaining of sensing the rocking motion of the boat after returning to ground. This usually resolves after the vestibular system becomes accustomed to the stationary influence of being back on land.

Motion sickness can usually be suppressed by supplying visual signals that more closely match the motion signals being supplied to the vestibular system. For example, looking out the window and watching the environment move when experiencing motion sickness associated with car travel provides the vestibular system with the visual sensation of motion, but reading a book provides the vestibular system with the mis cue that the environment is stable. Motion sickness usually decreases in severity with repeated exposure. Anti-motion sickness drugs also may be used to reduce or ameliorate the symptoms. These drugs work by suppressing the activity of the vestibular system.

Disorders of Peripheral Vestibular Function

Disorders of peripheral vestibular function occur when signals from the peripheral vestibular apparatus are distorted, as in BPPV, or are unbalanced by unilateral involvement of one of the vestibular organs, as in Ménière disease. The inner ear is vulnerable to injury caused by fracture of the petrous portion of the temporal bones; by infection of nearby structures, including the middle ear and meninges; and by blood-borne toxins and infections. Damage to the vestibular system can occur as an adverse effect of certain drugs or from allergic reactions to foods. The aminoglycosides (e.g., streptomycin, gentamicin) have a specific toxic affinity for the vestibular portion of the inner ear. Alcohol can cause transient episodes of vertigo. The cause of peripheral vertigo remains unknown in approximately half of the cases.

Severe irritation or damage of the vestibular end organs or nerves results in severe balance disorders reflected by instability of posture, ataxia, and falling accompanied by vertigo. With irritation, falling is away from the affected side. With destruction, it is toward the affected side. Adaptation to asymmetric stimulation occurs within a few days, after which the signs and symptoms diminish and eventually are lost. After recovery, there usually is a slightly reduced acuity for tilt, and the person walks with a somewhat broadened base to improve postural stability. The neurologic basis for this adaptation to unilateral loss of vestibular input is not understood. After adaptation to the loss of vestibular input from one side, the loss of function of the opposite vestibular apparatus produces signs and symptoms identical to those resulting from unilateral rather than bilateral loss. Within weeks, adaptation is again sufficient for locomotion and even for driving a car. Such a person relies heavily on visual and proprioceptive input from muscle and joint sensors and has severe orientation difficulty in the dark, particularly when traversing uneven terrain.

Benign Paroxysmal Positional Vertigo

BPPV is the most common cause of pathologic vertigo and usually develops after the fourth decade of life. It is characterized by brief periods of vertigo, usually lasting less than 1 minute, that are precipitated by a change in head position. The most prominent symptom of BPPV is vertigo that occurs in bed when the person rolls into a lateral position. It also commonly occurs when the person is getting in and out of bed, bending over and straightening up, or extending the head to look up. It also can be triggered by amusement rides that feature turns and twists.

### TABLE 24.1 DIFFERENCES IN PATHOLOGY AND MANIFESTATIONS OF DIZZINESS ASSOCIATED WITH BPPV, PRESYNCOPE, AND DISEQUILIBRIUM STATE

</tbody>
</table>
BPPV is thought to result from damage to the delicate sensory organs of the inner ear, the semicircular ducts, and the otoliths. BPPV is a common recurrence with people who have Ménière disease or have experienced head trauma.45 People experiencing BPPV have a movement of the otoliths from the utricle into the endolymph of the semicircular canal, which continue to move even when the head is stationary.44 Movement of the otoliths or free-floating debris causes this portion of the vestibular system to become more sensitive, such that any movement of the head in the plane parallel to the posterior duct may cause vertigo and nystagmus. There usually is a several-second delay between head movement and onset of vertigo, representing the time it takes to generate the exaggerated endolymph activity. Symptoms usually subside with continued movement, probably because the movement causes the debris to be redistributed throughout the endolymph system and away from the posterior semicircular canal.

Diagnosis is based on tests that involve the use of a change in head position to elicit vertigo and nystagmus, such as the Dix-Hallpike maneuver.45 BPPV often is successfully treated with drug therapy to control vertigo-induced nausea. Nondrug therapies using the rolling over maneuver and canalith repositioning are successful with many people.44 Canalith repositioning involves a series of maneuvers in which the head is moved to different positions in an effort to reposition the free-floating debris in the endolymph of the semicircular canals.44

**Acute Vestibular Neuronitis**

Acute vestibular neuronitis, or labyrinthitis, represents an inflammation of the vestibular nerve and is characterized by an acute onset generally within a couple of hours. Manifestations include vertigo, nausea, and vomiting lasting several days and not associated with auditory or other neurologic manifestations. Generally people resolve their problems in about 10 to 14 days. A large percentage of people report an upper respiratory tract illness 1 to 2 weeks before onset of symptoms, suggesting a viral origin. The condition also can occur in people with herpes zoster oticus. In some people, attacks of acute vestibulopathy recur over months or years. There is no way to determine whether a person who experiences a first attack will have repeated attacks.

**Ménière Disease**

Ménière disease is a disorder of the inner ear due to distention of the endolymphatic compartment of the inner ear. The classic triad of symptoms includes hearing loss, vertigo, and tinnitus.46 The primary lesion appears to be in the endolymphatic sac, which is thought to be responsible for endolymph filtration and excretion. A number of pathogenetic mechanisms have been postulated, including an increased production of endolymph, decreased production of perilymph accompanied by a compensatory increase in volume of the endolymphatic sac, and decreased absorption of endolymph caused by malfunction of the endolymphatic sac or blockage of endolymphatic pathways.

**Etiology.** The cause of Ménière disease is unknown, but it is known that this syndrome is a peripheral origin with vertigo.46 A number of conditions, such as trauma, infection, specific drugs (such as antibiotics), and toxins, have been identified as possible etiologies of Ménière disease.46 The most common form of the disease is an idiopathic form thought to be caused by a single viral injury to the fluid transport system of the inner ear. One area of investigation has been the relation between autoimmune disorders and Ménière disease.

**Clinical Manifestations.** Ménière disease is characterized by fluctuating episodes of tinnitus, feelings of ear fullness, and violent rotary vertigo that often renders the person unable to sit or walk. There is a need to lie quietly with the head fixed in a comfortable position, avoiding all head movements that aggravate the vertigo. Symptoms referable to the autonomic nervous system, including pallor, sweating, nausea, and vomiting, usually are present. The more severe the attack, the more prominent are the autonomic manifestations. A fluctuating hearing loss occurs with a return to normal after the episode subsides. Initially the symptoms tend to be unilateral, resulting in rotary nystagmus caused by an imbalance in vestibular control of eye movements. Because initial involvement usually is unilateral and because the sense of hearing is bilateral, many persons with the disorder are not aware of the full extent of their hearing loss. However, as the disease progresses, the person will experience worsening of hearing. The episodes of vertigo diminish and then disappear, although the person may be unsteady, especially in the dark.

**Diagnosis and Treatment.** Methods used in the diagnosis of Ménière disease include audiograms, vestibular testing by electronystagmography (ENG), and petrous pyramid radiographs. The administration of hyperosmolar substances, such as glycerin and urea, often produces acute temporary hearing improvement in persons with Ménière disease and sometimes is used as a diagnostic measure of endolymphatic hydrops. The diuretic furosemide also may be used for this purpose.

The management of Ménière disease focuses on attempts to reduce the distention of the endolymphatic space and can be medical or surgical. Pharmacologic management consists of suppressant drugs (e.g., prochlorperazine, promethazine, diazepam), which act centrally to decrease the activity of the vestibular system. Diuretics are used to reduce endolymph fluid volume. A low-sodium diet is recommended in addition to these medications. The steroid hormone, prednisone, may be used to maintain satisfactory hearing and resolve dizziness.

Surgical methods include the creation of an endolymphatic shunt in which excess endolymph from the inner ear is diverted into the subarachnoid space or the mastoid (endolymphatic sac surgery), and vestibular nerve section. Advances in vestibular nerve section have facilitated the monitoring of CN VII and CN VIII potentials.
Disorders of Central Vestibular Function

Abnormal nystagmus and vertigo can occur as a result of CNS lesions involving the cerebellum and lower brain stem. Central causes of vertigo include brain stem ischemia, tumors, and multiple sclerosis. When brain stem ischemia is the cause of vertigo, it usually is associated with other brain stem signs such as diplopia, ataxia, dysarthria, or facial weakness. Compression of the vestibular nuclei by cerebellar tumors invading the fourth ventricle results in progressively severe signs and symptoms. In addition to abnormal nystagmus and vertigo, vomiting and a broad-based and dystaxic gait become progressively more evident.

Centrally derived nystagmus usually has equal excursion in both directions (i.e., pendular). In contrast to peripherally generated nystagmus, CNS-derived nystagmus is relatively constant rather than episodic, can occur in any direction rather than being primarily in the horizontal or torsional (rotatory) dimensions, often changes direction through time, and cannot be suppressed by visual fixation. Repeated induction of nystagmus results in rapid diminution or “fatigue” of the reflex with peripheral abnormalities, but fatigue is not characteristic of central lesions. Abnormal nystagmus can make reading and other tasks that require precise eye positional control difficult.

Diagnosis and Treatment of Vestibular Disorders

**Diagnostic Tests**

Diagnosis of vestibular disorders is based on a description of the symptoms, a history of trauma or exposure to agents that are destructive to vestibular structures, and physical examination. Physical examination methods include use of the Romberg test, evaluation of gait, and observation for the presence of nystagmus. Other tests of vestibular function include ENG and the caloric stimulation test.

In peripheral lesions, nystagmus is usually horizontal and with a rotary component; the fast beat usually beats away from the disease side. Several types of maneuvers can be used to provoke vertigo and observe for nystagmus. Usually the examiner has the person sitting upright on an examining table with the head turned toward them with their eyes focused on the examiner’s finger. The person is then properly supported and lowered rapidly to the supine position with the head extending over the upper end of the examining table and placed about 30 degrees lower than the body. The person is observed for nystagmus for about 30 seconds while in that position. The test can be performed with the head turned to either side or with the person looking straight ahead.

Vertigo arising from central lesions tends to develop gradually, and nystagmus is not always present, can occur in any direction, and can be dissociated in the two eyes. ENG is often useful in documenting the characteristics of the nystagmus. Further evaluation of central vertigo usually requires MRI.

**Romberg Test.** The Romberg test is used to demonstrate disorders of static vestibular function. The person being tested is requested to stand with feet together and arms extended forward so that the degree of sway and arm stability can be observed. The person then is asked to close his or her eyes. When visual clues are removed, postural stability is based on proprioceptive sensation from the joints, muscles, and tendons and from static vestibular reception. Deficiency in vestibular static input is indicated by greatly increased sway and a tendency for the arms to drift toward the side of deficiency.

If vestibular input is severely deficient, the subject falls toward the deficient side. Care must be taken because defects of proprioceptive projection to the forebrain also result in some arm drift and postural instability toward the deficient side. Only if two-point discrimination and vibratory sensation from the lower and upper limbs are bilaterally normal can the deficiency be attributed to the vestibular system.

**Electronystagmography.** ENG is an examination that records eye movements in response to vestibular, visual, cervical (vertigo triggered by somatosensory input from head and neck movements), rotational, and positional stimulation. Electrodes are placed lateral to the outer canthus of each eye and above and below each eye. A ground electrode is placed on the forehead. With ENG, the velocity, frequency, and amplitude of spontaneous or induced nystagmus and the changes in these measurements brought by a loss of fixation, with the eyes open or closed, can be quantified. The advantages of ENG are that it is easily administered, is noninvasive, does not interfere with vision, and does not require head restraint.

**Caloric Stimulation.** Caloric testing involves elevating the head 30 degrees and irrigating each external auditory canal separately with 30 to 50 mL of ice water. The resulting changes in temperature, which are conducted through the petrous portion of the temporal bone, set up convection currents in the endolymph that mimic the effects of angular acceleration. In an unconscious person with a functional brain stem and intact oculoVESTIBULAR reflexes, the eyes exhibit a jerk nystagmus lasting 2 to 3 minutes, with the slow component toward the irrigated ear followed by rapid movement away from the ear. With impairment of brain stem function, the response becomes perverted and eventually disappears. An advantage of the caloric stimulation method is the ability to test the vestibular apparatus on one side at a time. The test is never done on persons who do not have an intact eardrum or who have blood or fluid collected behind the eardrum.

**Treatment**

**Pharmacologic Methods.** Depending on the cause, vertigo may be treated pharmacologically. There are two types of drugs used in the treatment of vertigo. The first type are the drugs used to suppress the illusion of motion. These include drugs such as antihistamines and anticholinergic drugs that suppress the vestibular system. Although the antihistamines have long been used in treating vertigo, little is known about
their mechanism of action. The second type includes drugs used to relieve the nausea and vomiting that commonly accompany the condition.

**Vestibular Rehabilitation Exercises.** Vestibular rehabilitation has been shown to be helpful as a treatment for peripheral vestibular disorders. Physical therapists are usually involved in developing a program including habituation exercises, balance retraining exercises, and a general conditioning program for people to use at home. The habituation exercises take advantage of physiologic fatigue of the neurovegetative response to repetitive movement or positional stimulation and are done to decrease motion-provoked vertigo, light-headedness, and unsteadiness. The exercises are selected to provoke the vestibular symptoms. The person moves quickly into the position that causes symptoms, holds the position until the symptoms subside (i.e., fatigue of the neurovegetative response), relaxes, and then repeats the exercise for a prescribed number of times. The exercises usually are repeated twice daily.

Balance-retraining exercises consist of activities directed toward improving individual components of balance that may be abnormal. General conditioning exercises, a vital part of the rehabilitation process, are individualized to the person’s preferences and lifestyle. It is recommended that the person practice these exercises about five times per week.

**IN SUMMARY**

The vestibular system plays an essential role in the equilibrium sense, which is closely integrated with the visual and proprioceptive (position) senses. Receptors in the semicircular canals, utricle, and saccule of the vestibular system, located in the inner ear, respond to changes in linear and angular acceleration of the head. The vestibular nerve fibers travel in CN VIII to the vestibular nuclei at the junction of the medulla and pons; some fibers pass through the nuclei to the cerebellum. Cerebellar connections are necessary for temporally smooth, coordinated movements during ongoing head movements, tilt, and angular acceleration. The vestibular nuclei also connect with nuclei of the oculomotor (CN III), trochlear (CN IV), and abducens (CN VI) nerves that control eye movement. Nystagmus is a term used to describe vestibular-controlled eye movements that occur in response to angular and rotational movements of the head. The vestibulospinal tract, which provides for the control of muscle tone in the axial muscles, including those of the back, provides the support for maintaining balance. Neurons of the vestibular nuclei also project to the thalamus, to the temporal cortex, and to the somesthetic area of the parietal cortex. The thalamic and cortical projections provide the basis for the subjective experiences of position in space and of rotation and vertigo.

Vertigo, an illusory sensation of motion of either oneself or one’s surroundings, tinnitus, and hearing loss are common manifestations of vestibular dysfunction, as are autonomic manifestations such as perspiration, nausea, and vomiting. Common disorders of the vestibular system include motion sickness, BPPV, and Ménière disease.

BPPV is a condition believed to be caused by free-floating particles in the posterior semicircular canal. It presents as a sudden onset of dizziness or vertigo that is provoked by certain changes in head position. Ménière disease, which is caused by an overaccumulation of endolymph, is characterized by severe, disabling episodes of tinnitus; feelings of ear fullness; and violent rotary vertigo. The diagnosis of vestibular disorders is based on a description of the symptoms, a history of trauma or exposure to agents destructive to vestibular structures, and tests of eye movements (i.e., nystagmus) and muscle control of balance and equilibrium. Among the methods used in treatment of the vertigo that accompanies vestibular disorders are habituation exercises and antivertigo drugs. These drugs act by diminishing the excitability of neurons in the vestibular nucleus.

**REVIEW EXERCISES**

1. A mother notices that her 13-month-old child is fussy and tugging at his ear, and he refuses to eat his breakfast. When she takes his temperature, it is 37.8°C (100°F). Although the child attends day care, the mother has kept him home and made an appointment with the child’s pediatrician. In the physician’s office, his temperature is 37.9°C (100.2°F), he is somewhat irritable, and he has a clear nasal drainage. His left tympanic membrane shows normal landmarks and motility on pneumatic otoscopy. His right tympanic membrane is erythematous, and there is decreased motility on pneumatic otoscopy.
   A. What risk factors are present that predispose this child to the development of AOM?  
   B. Are his signs and symptoms typical of OM in a child this age?  
   C. What are the most likely pathogens? What treatment would be indicated?  
   D. Later in the week, the mother notices that the child does not seem to hear as well as he did before developing the infection. Is this a common occurrence and should the mother be concerned about transient hearing loss in a child of this age?  

2. A granddaughter is worried that her grandfather is “losing his hearing.” Lately, he has been staying away from social gatherings that he always enjoyed, saying everybody mumbles. He is defiant in maintaining that there is nothing wrong with his hearing. However, he does complain that his ears have been ringing a lot lately.
A. What are common manifestations of hearing loss in older adults?
B. What type of evaluation would be appropriate for determining if this man has a hearing loss and the extent of his hearing loss?
C. What are some things that the granddaughter might do so that her grandfather could hear her better when she is talking to him?
3. A 70-year-old man complains that he gets this terrible feeling “like the room is moving around” and becomes nauseated when he rolls over in bed or bends over suddenly. It usually goes away once he has been up for a while. He has been told that his symptoms are consistent with BPPV.
A. What is the pathophysiology associated with this man’s vertigo?
B. Why do the symptoms subside once he has been up for a while?
C. What methods are available for treatment of the disorder?

Mrs. Cretena, a 48-year-old woman, presents for her annual physical examination. She complains of fatigue and heavy menses over the last 6 months. She has four children and works full-time so she had not really thought much of the fatigue until she talked to a friend who recommended that she should have her hemoglobin level tested. Her laboratory data reflected the following: RBC = 4.2 × 10⁶/mm³ (3.6 to 5.0 × 10⁶/mm³ for women), hematocrit = 35% (36% to 48% [women]), and hemoglobin = 10 g/dL (12.0 to 16.0 g/dL). Her red blood cell indices indicated a microcytic hemochromic anemia. She was told she had iron deficiency anemia and was told to take ferrous sulfate TID and return for a follow-up in 2 weeks.
Blood is a specialized connective tissue that consists of blood cells (red blood cells, white blood cells, and platelets) suspended in an extracellular fluid, known as plasma. Blood accounts for about 7% to 8% of total body weight. The total volume of blood in the average adult is about 5 to 6 L, and it circulates throughout the body within the confines of the circulatory system. Because blood circulates throughout the body, it is an ideal vehicle for transport of materials to and from the many cells of the body.

**DIAGNOSTIC TESTS**
- Blood Count
- Erythrocyte Sedimentation Rate
- Bone Marrow Aspiration and Biopsy

After completing this section of the chapter, you should be able to meet the following objectives:

- Describe the composition and functions of plasma.
- Describe the formed elements of blood and cite their function and life span.
- Trace the process of hematopoiesis from stem cell to mature blood cell.

When blood is artificially removed from the body for testing or when blood exits the body due to vascular injury, it clots within 30 to 60 minutes. The clot contains the blood’s cellular components enmeshed in an insoluble fibrin network formed by the polymerization of the soluble plasma protein fibrinogen. The remaining fluid portion of clotted blood is the yellow liquid serum. This serum no longer contains fibrinogen as the fibrinogen is consumed in the formation of the blood clot. Addition of an anticoagulant (e.g., heparin, citrate) to blood removed from the circulation via phlebotomy creates a whole blood specimen. When a whole blood specimen is centrifuged, it will separate into three distinct layers (Fig. 25.1).

The bottom layer (approximately 42% to 47% of the whole blood volume) contains the erythrocytes or red blood
cells (RBCs). The hematocrit is the blood test, which is the ratio of this volume of packed RBCs in the bottom layer to the total blood volume within the test tube. The intermediate fluffy-looking layer (approximately 1%) containing the leukocytes, or white blood cells, is white or gray and is called the buffy coat. Above the leukocytes is a thin layer of thrombocytes or platelets that is not discernible to the naked eye. The translucent, yellowish fluid that forms on the top of the cells is the plasma, which comprises approximately 55% of the total volume. The major difference between plasma and serum is the presence of fibrinogen in the plasma from an anticoagulated centrifuged whole blood specimen. Serum does not contain fibrinogen because the fibrinogen originally present in uncoagulated blood was used in the formation of the clot.

**COMPOSITION OF THE BLOOD**

- The most abundant of the blood cells, the erythrocytes or RBCs, function in oxygen and carbon dioxide transport.
- The leukocytes, or white blood cells, serve various roles in immunity and inflammation.
- Platelets are small cell fragments that are involved in blood clotting.

**Plasma**

Plasma, a liquid, is 90% to 91% water by weight, 6.5% to 8% proteins by weight, and 2% other small molecular substances (Table 25.1). Plasma water serves as a transport vehicle for materials carried in the blood. As a transport medium, plasma carries nutrients from the gastrointestinal tract and oxygen from the lungs to body cells while picking up waste products from the cells for delivery to excretory organs. It also transports hormones and facilitates the exchange of chemical mediators. Plasma participates in electrolyte and acid–base balance, and it contains the plasma proteins that contribute to the osmotic regulation of body fluids. In addition, because water has a high capacity to hold heat, plasma can absorb and distribute much of the heat that is generated in the body.

**Plasma Proteins**

The plasma proteins are the most abundant solutes in plasma. It is the presence of these proteins that distinguish the composition of plasma from that of interstitial fluid. The major types of plasma proteins are albumin, globulins, and fibrinogen. Except for the blood-borne hormones and gamma globulins, most plasma proteins are produced by the liver, which secretes them into the blood. Albumin is the most abundant and makes up approximately 54% of the plasma proteins. It does not pass through the pores in the capillary wall to enter...
the interstitial fluid and therefore contributes to the plasma osmotic pressure and maintenance of blood volume. Albumin also serves as a carrier for certain substances and acts as a blood buffer.

The globulins comprise approximately 38% of plasma proteins. There are three types of globulins—the alpha globulins that transport bilirubin and steroids, the beta globulins that transport iron and copper, and the gamma globulins that constitute the antibodies of the immune system.

Fibrinogen makes up approximately 7% of the plasma proteins. Fibrinogen is a soluble protein that polymerizes to form the insoluble protein fibrin during blood clotting. The remaining 1% of the circulating proteins are hormones, enzymes, complement, and carriers for lipids.

Blood Cells

The blood cells, including the erythrocytes, leukocytes, and platelets, originate in the bone marrow. Figure 25.2 illustrates a blood smear. The blood cells, or formed elements, are not all true cells. Erythrocytes have no nuclei or organelles and platelets are just cell fragments. Most blood cells do not divide. Therefore, division of cells in the bone marrow must continually renew them. Table 25.2 lists the normal values for the blood cells.

Erythrocytes

The erythrocytes, or RBCs, are the most numerous of the formed elements. They are small, biconcave disks having an average diameter of 7.8 µm and a thickness of approximately 2.5 µm. The mean volume of an average RBC is approximately 90 µm³. RBCs have a large surface area and can easily deform into just about any shape to move through the small capillaries of the circulatory system. They contain the oxygen-carrying protein, hemoglobin, that functions in the transport of oxygen. RBCs can concentrate hemoglobin in the cell fluid up to approximately 34 grams in each 100 mL of cells.

Ninety percent of the erythrocytes, which have their origin in the bone marrow, live approximately 120 days in the circulation and then are phagocytosed in the bone marrow, spleen, and liver. The other 10% of RBCs break down and excrete little amounts of hemoglobin into the circulatory system. Erythrocyte precursors in the bone marrow possess nuclei, but expel not only their nuclei but also all organelles before entering the circulation. Although erythrocytes have no organelles, they have soluble enzymes, including carbonic anhydrase, within their cytosol. This enzyme facilitates the formation of carbonic acid from carbon dioxide and water, which in turn dissociates into bicarbonate and hydrogen ions. Thus, erythrocytes also contribute to carbon dioxide transport and regulation of acid–base balance and are considered a superior acid–base buffer.

Leukocytes

The leukocytes, or white blood cells, are 10 to 12 µm in diameter and thus much larger than RBCs. However, they constitute only 1% of the total blood volume. They originate in the bone marrow and circulate throughout the lymphoid tissues of the body. Leukocytes are crucial to our defense against disease in the following ways:

- They are responsible for the immune response that protects against disease-causing microorganisms.
- They identify and destroy cancer cells.
- They participate in the inflammatory response and wound healing.

Leukocytes are commonly classified into two groups based on presence or absence of specific prominent granules in their cytoplasm (Fig. 25.3). Those containing specific granules (neutrophils, eosinophils, basophils) are classified as granulocytes and those that lack granules (lymphocytes and monocytes) as agranulocytes.

Granulocytes. Granulocytes are spherical and have distinctive multilobular nuclei. They are all phagocytic cells that are identifiable because of their cytoplasmic granules. They have two types of granules—the specific granules that bind neutral, basic, or acidic dye components and azurophilic granules. The azurophilic granules stain purple and are lysosomes. The granulocytes are divided into three types—neutrophils, eosinophils, and basophils—according to the staining properties of their specific granules.

**RBC INDICES**
- MCV (mean corpuscular volume) 80–100 fl.
- MCH (mean cell hemoglobin) 27–34 pg/cell.
- MCHC (mean corpuscular hemoglobin concentration) 31–35 g/dL.

**Neutrophils.** The neutrophils, which constitute 55% to 65% of the total white blood cells, have granules that are neutral and hence do not stain with an acidic or a basic dye. Because these white cells have nuclei that are divided into three to five lobes, they are often called polymorphs or polymorphonuclear leukocytes or PMNs.

The neutrophils are primarily responsible for maintaining normal host defenses against invading bacteria and fungi, cell debris, and a variety of foreign substances. The cytoplasm of mature neutrophils has three types of granules:

1. Small specific granules that contain complement activators and bacteriostatic and bacteriocidal agents
2. Larger azurophilic granules that contain peroxidases and other hydrolytic enzymes
3. Newly discovered tertiary granules, which contain proteins thought to facilitate movement and migration of the neutrophil

Neutrophils are very mobile and are the first cells to go to an area of tissue damage. Their migration is a result of the release of adhesion molecules on the neutrophil surface, which connects with ligands on the endothelial cells. The neutrophils have their origin in the myeloblasts that are found in the bone marrow (Fig. 25.4). The myeloblasts are the committed precursors of the granulocyte pathway and do not normally appear in the peripheral circulation. When they are present, it suggests a disorder of blood cell proliferation and differentiation. The myeloblasts differentiate into promyelocytes and then myelocytes. Usually, a cell is not called a myelocyte until it has at least 12 granules. The myelocytes mature to become metamyelocytes, at which point they lose their capacity for mitosis. Subsequent development of the neutrophil involves reduction in size, with transformation from an oval to a horseshoe-shaped nucleus (i.e., band cell) and then to a mature cell with a segmented nucleus. Mature neutrophils are often referred to as segs because of their segmented nucleus. Development from stem cell to mature neutrophil takes approximately 2 weeks. It is at this point that the neutrophil enters the bloodstream. Neutrophilia is an increase in...
UNIT VII Disorders of the Hematopoietic System

immature neutrophils ("band" forms) seen in the peripheral blood. It is most commonly seen in acute infections and tissue injuries that promote the accelerated release of neutrophils and their precursors into the circulation.

After release from the marrow, the neutrophils spend only approximately 4 to 8 hours in the circulation before moving into the tissues. They survive in the tissues for approximately 4 to 5 days. They die in the tissues by discharging their phagocytic function or from senescence. The pool of circulating neutrophils (i.e., those that appear in the blood count) is in a closely maintained equilibrium with a similar-sized pool of cells marginating along the walls of small blood vessels. These are the neutrophils that respond to chemotactic factors and migrate into the tissues toward the offending agent. Epinephrine, exercise, stress, and corticosteroid drug therapy can cause rapid increases in the circulating neutrophil count by shifting cells from the marginating to the circulating pool. Endotoxins or microbes have the opposite effect, producing a transient decrease in neutrophils by attracting neutrophils into the tissues.

**Eosinophils.** Eosinophils are similar in size to neutrophils. The specific cytoplasmic granules of the eosinophils stain red with the acidic dye eosin. These leukocytes constitute 1% to 3% of the total white blood cells and increase in number during allergic reactions and parasitic infections. In allergic reactions, it is thought that they release enzymes or chemical mediators that detoxify the agents associated with allergic reactions. Eosinophils release arylsulfatase and histaminases at sites of allergic reactions, and this is thought to decrease the potential negative impact of mediators that are released with inflammation. In parasitic infections, the eosinophils use surface markers to attach themselves to the parasite and then release hydrolytic enzymes that kill it. Therefore, with people who have allergic reactions and/or helminthic parasites, there will be an increase in eosinophils in the CBC. People with eosinophilic gastrointestinal diseases (EGID) have a profuse eosinophilic concentration in their GI mucosa, which have been found to cause pathology. However, no specific etiological immunoregulatory process can be identified.

**Basophils.** The basophils, also of similar size to neutrophils, are the least numerous of the white blood cells, accounting for only 0.3% to 0.5% of the total leukocytes. The specific granules of the basophils stain blue with a basic dye. These granules contain heparin, an anticoagulant; histamine, a vasodilator; and other mediators of inflammation such as leukotriene that cause bronchoconstriction of smooth muscles in pulmonary airways. The basophil, which is a blood cell, is related to, but not identical with, the connective tissue mast cell that contains similar granules. Both the basophils and mast cells are thought to be involved in allergic and hypersensitivity reactions.

**Lymphocytes.** Lymphocytes are the most common agranulocytes and account for 20% to 30% of the total blood leukocytes. They originate in the bone marrow from lymphoid stem cells and are the main functional cells of the immune system. They move between blood and lymph tissue, where they may be stored for hours or years. Their function in the lymph nodes or spleen is to defend against microorganisms through the immune response.

There are three types of lymphocytes—B lymphocytes, T lymphocytes, and natural killer cells. The B lymphocytes (B cells) are so named because they were first recognized as a separate population in the bursa of Fabricius in birds and bursa-equivalent organs (e.g., bone marrow) in mammals. They differentiate to form antibody-producing plasma cells and are involved in humoral-mediated immunity. The T lymphocytes (T cells) differentiate in the thymus. They activate other cells of the immune system (helper T cells) and are involved in cell-mediated immunity (cytotoxic T cells). Natural killer (NK) cells participate in innate or natural immunity and their function is to destroy foreign cells. The lymphocytes of the three different subsets have unique surface markers that can be identified and help to define their function and diagnose disease. The breakdown of lymphocytes includes 80% T cells, 10% B cells, and 10% NK cells. Major histocompatibility antigens, also known as human leukocyte antigens (HLAs), are expressed on lymphocytes and are responsible for multiple aspects of the human immunological response.
Monocytes and Macrophages. Monocytes are the largest of the white blood cells and constitute approximately 3% to 8% of the total leukocyte count. They are distinguished by a large amount of cytoplasm and a dark-stained nucleus in the shape of a kidney. The life span of the circulating monocyte is approximately 1 to 3 days, three to four times longer than that of the granulocytes. These cells survive for months to years in the tissues. The monocytes, which are precursors of the mononuclear phagocyte system, are often referred to as macrophages when they enter the tissues. The monocytes engulf larger and greater quantities of foreign material than the neutrophils. These leukocytes play an important role in chronic inflammation and are also involved in the immune response by activating lymphocytes and by presenting antigen to T cells. When the monocyte leaves the vascular system and enters the tissues, it functions as a macrophage with specific activity. The macrophages are known as histiocytes in loose connective tissue, microglial cells in the brain, and Kupffer cells in the liver. Other macrophages function in the alveoli, lymph nodes, and other tissues.

Granulomatous inflammation is a distinctive pattern of chronic inflammation in which the macrophages form a capsule around insoluble materials that cannot be digested. Relatively inert foreign bodies, such as talc or surgical sutures, incite foreign body granulomas. Immune granulomas are caused by insoluble particles that are capable of inciting a cell-mediated immune response. The tubercle that forms in primary tuberculosis infections is an example of an immune granuloma.

Thrombocytes

Thrombocytes, or platelets, are circulating cell fragments of the large megakaryocytes that are derived from the myeloid stem cell. They function to form the platelet plug to help control bleeding after injury to a vessel wall (Fig. 25.5). Their cytoplasmic granules release mediators required for the blood coagulation process. Thrombocytes have a membrane but no nucleus, cannot replicate, and, if not used, last approximately 10 days in the circulation before the phagocytic cells of the spleen remove them.

Formation of Blood Cells (Hematopoiesis)

The generation of blood cells takes place in the hematopoietic (from the Greek haima, “blood,” and poiesis, “making”) system. The hematopoietic system encompasses all of the blood cells and their precursors, the bone marrow where blood cells have their origin, and the lymphoid tissues where some blood cells circulate as they develop and mature.

Hematopoiesis begins in the endothelial cells of the developing blood vessels during the 5th week of gestation and then continues in the liver and spleen. After birth, this function is gradually taken over by the bone marrow. Some hematopoiesis may also occur in the spleen and the liver. The marrow is a network of connective tissue containing immature blood cells. At sites where the marrow is hematopoietically active, it
produces so many erythrocytes that it is red, hence the name red bone marrow. Fat cells are also present in bone marrow, but they are inactive in terms of blood cell generation. The fat cell can be visualized in the bone marrow in Figure 25.6. Marrow that is made up predominantly of fat cells is called yellow bone marrow. During active skeletal growth, red marrow is gradually replaced by yellow marrow in most of the long bones. In adults, red marrow is largely restricted to the flat bones of the pelvis, ribs, and sternum. When the demand for red cell replacement increases, as in hemolytic anemia, there can be resubstitution of red marrow for yellow marrow.

**Blood Cell Precursors**

The blood-forming population of bone marrow is made up of three types of cells—self-renewing stem cells, differentiated progenitor (parent) cells, and functional mature blood cells. All of the blood cell precursors of the erythrocyte (i.e., red cell), myelocyte (i.e., granulocyte or monocyte), lymphocyte (i.e., T lymphocyte and B lymphocyte), and megakaryocyte (i.e., platelet) series are derived from a small population of primitive cells called the pluripotent stem cells (Fig. 25.7). Their lifelong potential for proliferation and self-renewal makes them an indispensable and lifesaving source of reserve cells for the entire hematopoietic system. Several levels of differentiation lead to the development of committed unipotential cells, which are the progenitors for each of the blood cell types. These cells are referred to as colony-forming units (CFUs). These progenitor cells have only limited capacity for self-renewal but retain the potential to differentiate into lineage-specific precursor cells. Precursor cells have morphologic characteristics that permit them to be recognized as the first cell of a particular cell line. They have lost their ability for self-renewal but undergo cell division and differentiation, eventually giving rise to mature lymphocytes, myelocytes, megakaryocytes, or erythrocytes.¹

**KEY POINTS**

**HEMATOPOIESIS**

- White blood cells are formed from hematopoietic stem cells that differentiate into committed progenitor cells that in turn develop into the myelogenous and lymphocytic lineages needed for the formation of the different types.
- The growth and reproduction of the different stem cells is controlled by CSFs and other cytokines and chemical mediators.
Regulation of Hematopoiesis

Under normal conditions, the numbers and total mass for each type of circulating blood cell remain relatively constant. The blood cells are produced in different numbers according to needs and regulatory factors. This regulation of blood cells is thought to be at least partially controlled by hormone-like growth factors called cytokines. The cytokines are a family of short-lived mediators that stimulate the proliferation, differentiation, and functional activation of the various blood cells.

Many cytokines derived from lymphocytes or bone marrow stromal cells stimulate the growth and production of new blood cells. Several members of this family are called colony-stimulating factors (CSFs) because of their ability to promote the growth of hematopoietic cell colonies in the laboratory. The CSFs that act on committed progenitor cells include erythropoietin (EPO), which stimulates RBC production; granulocyte-macrophage colony-stimulating factor (GM-CSF), which stimulates progenitors for granulocytes, monocytes, and macrophages; granulocyte colony-stimulating factor (G-CSF), which promotes the proliferation of neutrophils; macrophage colony-stimulating factor (M-CSF), which induces macrophage colonies; and thrombopoietin (TPO), which stimulates the differentiation of platelets. Other cytokines, such as the interleukins, interferons, and tumor necrosis factor, support the proliferation of stem cells and the development of lymphocytes and act synergistically to aid the multiple functions of the CSFs.

The genes for most hematopoietic growth factors have been cloned and their recombinant proteins have been generated for use in a wide range of clinical problems. Some examples of the clinically useful factors include EPO, TPO, G-CSF, and GM-CSF. They are used to treat bone marrow failure caused by chemotherapy or aplastic anemia, the anemia of kidney failure and cancer, hematopoietic neoplasms, infectious diseases such as acquired immunodeficiency syndrome (AIDS), and congenital and myeloproliferative disorders. Growth factors are used to increase peripheral stem cells for transplantation and to accelerate cell proliferation after bone marrow engraftment. Many of these uses are still investigational and new factors are being created.

Disorders of Hematopoietic Stem Cells

Underproliferation of the stem cell population may result in failure to produce one or several cell types. For example, aplastic anemia develops when the multipotent stem cells

FIGURE 25.7 • Major maturational stages of blood cells. (CFU, colony-forming unit; NK, natural killer cell.)
fail to grow and provide cells for differentiation. The result is concomitant anemia, thrombocytopenia, and granulocytopenia (pancytopenia). On the other hand, the myeloproliferative diseases are characterized by a hypercellular bone marrow and a tendency to elevated peripheral blood counts. Unregulated overproduction of the red cell mass is termed polycythemia. Thrombocytosis occurs when the bone marrow produces too many platelets. Leukemias represent a spectrum of diseases characterized by an abnormal proliferation of white blood cells.

Potential cures for these and many other disorders use hematopoietic stem cells as part of the treatment. Many people with leukemia obtain stem cell transplants that greatly impact their ability to have a remission. Stem cell transplants focus on correcting bone marrow failure, immunodeficiencies, hematologic defects and malignancies, and inherited errors of metabolism. Sources of the stem cells include bone marrow and umbilical cord blood, which replenish the recipient with a normal population of pluripotent stem cells. Stem cell transplants may be derived from the patient (autologous) or from a histocompatible donor (allogeneic). Autologous transplants are often used to replenish stem cells after high-dose chemotherapy or irradiation. Umbilical cord blood from HLA-matched donors is a transplant option for children and carries less risk of graft-versus-host disease. See Chapters 26, 27, and 28 for a more detailed description of the pathogenesis, clinical manifestations, and treatment of these stem cell disorders.

**Blood Count**

The blood count provides information regarding the number of blood cells and their structural and functional characteristics. A complete blood count (CBC) is a commonly performed screening test that determines the number of RBCs, white blood cells, and platelets per unit of blood. The white cell differential count is the determination of the relative proportions (percentages) of individual white cell types. Measurements of hemoglobin, hematocrit, mean corpuscular volume (MCV), mean corpuscular hemoglobin concentration (MCHC), and mean cell hemoglobin (MCH) are usually included in the CBC. These last three tests, MCV, MCHC, and MCH, are called the RBC indices. Inspection of the blood smear identifies morphologic abnormalities such as a change in size, shape, or color of cells. These indices are often used to determine what type of anemia a person has.

**Erythrocyte Sedimentation Rate**

The erythrocyte sedimentation rate (ESR) is a screening test for monitoring the fluctuations in the clinical course of a disease such as chronic fatigue syndrome, lupus erythematosus, or polymyalgia rheumatica (PMR). Symptoms of these inflammatory disorders include fatigue, fever, and headache, which are all a result of the systemic effects of cytokine release. Increased sedimentation rate indicates inflammation and is used as a baseline and trend indicator in managing, for example, PMR. An individual is diagnosed with PMR and will have an initial ESR drawn. If the ESR is > 60 the person is diagnosed with a more severe PMR than if the person had an elevated ESR of 40. Generally, the person is prescribed prednisone, and then at follow-up visits, the dose of prednisone will be gradually decreased depending on the ESR and the person’s symptoms.

In anticoagulated blood, RBCs aggregate and sediment to the bottom of a tube. The rate of fall of the aggregates is regulated by chemical messengers called cytokines (interleukins, interferons, and others) and growth factors (CSFs).
Bone Marrow Aspiration and Biopsy

Tests of bone marrow function are done on samples obtained using bone marrow aspiration or bone marrow biopsy. Bone marrow aspiration is performed with a special needle inserted into the bone marrow cavity, through which a sample of marrow is withdrawn. Usually, the posterior iliac crest is used in all people older than 12 to 18 months of age. Other sites include the anterior iliac crest, sternum, and spinous processes T10 through L4. The sternum is not commonly used in children because the cavity is too shallow and there is danger of mediastinal and cardiac perforation. Because aspiration disturbs the marrow architecture, this technique is used primarily to determine the type of cells present and their relative numbers for diagnostic purposes. Stained smears of bone marrow aspirates are usually subjected to several studies, including determination of the erythroid to myeloid cell count (i.e., normal ratio is 1:3), differential cell count, search for abnormal cells, evaluation of iron stores in reticulum cells, and special stains and immunohistochemical studies.

Bone marrow biopsy is done with a special biopsy needle inserted into the posterior iliac crest. It is likely a bone marrow biopsy versus a bone marrow aspiration will need to be performed to diagnose an acute leukemia since there are so many white blood cells in the marrow the aspirate procedure may not obtain a specimen. This would also be true with someone who was pancytopenic and there is little to no hematopoietic activity. Biopsy removes an actual sample of bone marrow tissue and allows study of the architecture of the tissue. It is used to determine the marrow-to-fat ratio and the presence of fibrosis, plasma cells, granulomas, and cancer cells. The major hazard of these procedures is the slight risk of hemorrhage. This risk is increased in people with a reduced platelet count or any type of bleeding dyscrasia.

IN SUMMARY

Diagnostic tests of the blood include the CBC, the ESR, and bone marrow aspiration and biopsy. The CBC is used to describe the number and characteristics of the erythrocytes, leukocytes, and platelets. The ESR is used to detect inflammation. Bone marrow aspiration is removal of the fluid portion of marrow from within the bone marrow cavity. Bone marrow aspirate analysis focuses on cellular morphology and determination of a differential cell count. A bone marrow biopsy removes a sample of solid bone marrow, which permits study of the marrow’s overall cellularity and detection of focal lesions and the extent of the marrow by pathologic processes.

**Hemostasis** refers to the stoppage of blood flow. The normal process of hemostasis is regulated by a complex array of activators and inhibitors that maintain blood fluidity and prevent blood from leaving the vascular compartment. Hemostasis is normal when it seals a blood vessel to prevent blood loss and hemorrhage. It is abnormal when it causes inappropriate blood clotting or when clotting is insufficient to stop the flow of blood from the vascular compartment. Disorders of hemostasis fall into two main categories—the inappropriate formation of clots within the vascular system (thrombosis) and the failure of blood to clot in response to an appropriate stimulus (bleeding).

Hemostasis is divided into three stages:

1. Vascular constriction
2. Formation of the platelet plug
3. Blood coagulation

During the process of hemostasis, hairlike fibrin strands glue the aggregated platelets together to form the structural basis of the blood clot. In the presence of fibrin, plasma becomes gel-like and traps red blood cells and other formed elements in the blood. Hemostasis is complete when fibrous tissue grows into the clot and seals the hole in the vessel.
**Vascular Constriction**

Vessel spasm constricts the vessel and reduces blood flow. It is a transient event that usually lasts minutes or hours.² Vessel spasm is initiated by endothelial injury and caused by local and humoral mechanisms. Neural reflexes and thromboxane A₂ (TXA₂), a prostaglandin released from platelets, and other mediators such as serotonin contribute to vasoconstriction.² The most powerful vasoconstrictor is endothelin 1.¹

Prostacyclin, another prostaglandin released from the vessel endothelium, produces vasodilation and inhibits platelet aggregation in the surrounding uninjured endothelium.²

**Formation of the Platelet Plug**

The platelet plug, the second line of defense, is initiated as platelets come in contact with the vessel wall. Small breaks in the vessel wall are often sealed with the platelet plug rather than a blood clot.

Platelets, or thrombocytes, are large fragments from the cytoplasm of bone marrow cells called megakaryocytes.¹ The platelet has a half-life of approximately 8 to 12 days, and then it is broken down and eliminated by macrophages.¹ The normal serum concentration is about 150,000 to 400,000 platelets per microliter (µL) of blood.¹ Platelet production is controlled by a protein called thrombopoietin that causes proliferation and maturation of megakaryocytes.³ The sources of thrombopoietin include the liver, kidney, smooth muscle, and bone marrow.

Platelets have a cell membrane but no nucleus, and cannot reproduce. The cell membrane has phospholipids that assist with the coagulation process. Although they lack a nucleus, they have many of the characteristics of a whole cell. The outer cell membrane is covered with a coat of glycoproteins, glycosaminoglycans, and coagulation proteins (Fig. 26.2). One of the important glycoproteins is GPIIb/IIIa, which binds fibrinogen and bridges platelets to one another.² The platelet shape is maintained by microtubules and actin and myosin filaments that support the cell membrane. Platelets have mitochondria and enzyme systems capable of producing adenosine triphosphate (ATP) and adenosine diphosphate (ADP). They also have the enzymes needed for synthesis of the prostaglandin, TXA₂, required for their function in hemostasis.

Platelets contain two specific types of granules (α- and δ-granules) that release mediators for hemostasis.²⁴ The α-granules express the P selectin, an adhesive protein, on their surface and contain fibrinogen, von Willebrand factor (vWF), fibronectin, factors V and VIII, platelet factor 4 (a heparin-binding chemokine), platelet-derived growth factor (PDGF), transforming growth factor-alpha (TGF-α), and thrombospondin.²⁴ The release of growth factors results in the proliferation and growth of vascular endothelial cells, smooth muscle cells, and fibroblasts and is important in vessel repair.

The δ-granules, or dense granules, contain ADP and ATP, ionized calcium, histamine, serotonin, and epinephrine, which contribute to vasoconstriction.³

Platelet plug formation involves adhesion and aggregation of platelets. Platelets are attracted to a damaged vessel
but interact with injured areas of the vessel wall and the deeper exposed collagen. Glycoprotein (GPIIb/IIIa) receptors on the platelet membrane bind fibrinogen and link platelets together. Defective platelet plug formation causes bleeding in people who are deficient in platelets or vWF. In addition to sealing vascular breaks, platelets play an almost continuous role in maintaining normal vascular integrity. They may supply growth factors for endothelial and arterial smooth muscle cells. People with platelet deficiency have increased capillary permeability and sustain small skin hemorrhages from the slightest trauma or change in blood pressure.

Platelet aggregation inhibitors, including aspirin, clopidogrel (Plavix), and ticlopidine (Ticlid), can be used to prevent platelet aggregation and clot formation in people who are at risk for myocardial infarction, stroke, or peripheral artery disease. Low-dose aspirin therapy inhibits prostaglandin synthesis, including TXA₂. Clopidogrel and ticlopidine achieve their antplatelet effects by inhibiting the ADP pathway in platelets. Unlike aspirin, these drugs have an effect on prostaglandin synthesis. Both clopidogrel and ticlopidine prolong the bleeding time. However, the most serious side effects of ticlopidine have been neutropenia and thrombotic thrombocytopenic purpura. Studies from randomized trials have shown that clopidogrel in combination with aspirin is associated with a reduction in major cardiac events, similar to ticlopidine plus aspirin, and appeared safer. The Antiplatelet Therapy Guidelines jointly published by the American Heart Association and the American College of Cardiology have been updated to suggest that the use of proton pump inhibitor with antiplatelet therapy, specifically clopidogrel, may cause cardiac adverse effects due to a cytochrome P450 drug interaction. So, although adding a proton pump inhibitor with most antiplatelet therapy seems to be efficacious, it is recommended that clopidogrel be used without a proton pump inhibitor due to potential negative cardiovascular side effects.

Drugs that act as GPIIb/IIIa receptor inhibitors (tiropidil, epifibatide, abciximab) have been developed for use in the treatment of acute coronary syndromes. However, acute and delayed thrombocytopenia has been reported after use of these agents, suggesting that further investigation is needed to understand the mechanisms leading to the thrombocytopenia and improve methods for detection of this complication.

**KEY POINTS**

**HEMOSTASIS**

- Hemostasis is the orderly, stepwise process for stopping bleeding that involves vasoconstriction, formation of a platelet plug, and the development of a fibrin clot.
- The blood clotting process requires the presence of platelets produced in the bone marrow, vWF generated by the vessel endothelium, and clotting factors synthesized in the liver, using vitamin K.
Blood Coagulation

The coagulation cascade is part of the hemostatic process. It is a stepwise process resulting in the conversion of the soluble plasma protein, fibrinogen, into fibrin. The insoluble fibrin strands create a meshwork that cements platelets and other blood components together to form the clot.

Many substances that promote clotting (procoagulation factors) or inhibit it (anticoagulation factors) control the coagulation process. Each of the procoagulation or coagulation factors, identified by Roman numerals, performs a specific step in the coagulation process. The activation of one procoagulation factor or proenzyme is designed to activate the next factor in the sequence (cascade effect). Because most of the inactive procoagulation factors are present in the blood at all times, the multistep process ensures that a massive episode of intravascular clotting does not occur. It also means that abnormalities of the clotting process occur when one or more of the factors are deficient or when conditions lead to inappropriate activation of any of the steps.

Most of the coagulation factors are proteins synthesized in the liver. Vitamin K is necessary for the synthesis of factors II, VII, IX, and X, prothrombin, and protein C. If there is a deficiency of vitamin K or liver failure so that not enough prothrombin is created, a bleeding tendency will develop. Calcium (factor IV) is required in all but the first two steps of the clotting process. The body usually has sufficient amounts of calcium for these reactions. Inactivation of the calcium ion prevents blood from clotting when it is removed from the body. The addition of citrate to blood stored for transfusion purposes prevents clotting by chelating ionic calcium. Ethylenediaminetetraacetic acid (EDTA), another chelator, is often added to blood samples used for analysis in the clinical laboratory.

The coagulation process results from the activation of what have traditionally been designated the intrinsic and the extrinsic pathways, both of which form prothrombin activator (Fig. 26.3). The intrinsic pathway, which is a relatively slow process (can cause clotting in 1 to 6 minutes), begins in the circulation with the activation of factor XII. The extrinsic pathway, which is a much faster process (can cause clotting in 15 seconds), begins with trauma to the blood vessel or surrounding tissues and the release of tissue factor or tissue thromboplastin, an adhesive lipoprotein, from the subendothelial cells. It is composed of phospholipids from the membranes along with a lipoprotein complex that acts as a proteolytic enzyme. The terminal steps in both pathways are the same—the activation of factor X and the conversion of prothrombin to thrombin. Thrombin then acts as an enzyme to convert fibrinogen to fibrin, the material that stabilizes a clot.

Blood coagulation is regulated by several natural anticoagulants. Antithrombin III inactivates coagulation factors

![Figure 26.3](image-url)
and neutralizes thrombin, the last enzyme in the pathway for the conversion of fibrinogen to fibrin. When antithrombin III is complexed with naturally occurring heparin, its action is accelerated to inactivate thrombin, factor Xa, and other coagulation factors. This complex activation provides protection against uncontrolled thrombus formation on the endothelial surface.¹

Protein C, a plasma protein, acts as an anticoagulant by inactivating factors V and VIII. Protein C or PC antigen (factor V Leiden) is produced in the liver and prevents thrombosis. Protein C deficiency is 35% to 58% congenital, but can also be acquired if one has severe liver failure, vitamin K deficiency, or malignancy.⁸ This disorder is an inherited defect in factor V and causes increased risk for clotting. It is able to be measured by a protein C resistance test, and the normal range should be between 0.60 and 1.25 of normal PC antigen.⁸ Women with factor V Leiden combined with the prothrombotic influence of pregnancy are at high risk for adverse pregnancy outcomes such as venous thromboembolism disorders, preeclampsia, fetal loss, and placental abruption.⁹

Protein S, another plasma protein, accelerates the action of protein C. A deficiency of either protein C or S puts one at risk for thrombosis. A protein S test is performed to determine if the deficiency is inherited or acquired since often people with autoimmune disorders are at risk for protein S deficiency.⁸ The normal range for females is 0.50 to 1.20 of normal activity, and for males the range is 0.60 to 1.30.⁸

Plasmin breaks down fibrin into fibrin degradation products that act as anticoagulants. It has been suggested that some of these natural anticoagulants may play a role in the bleeding that occurs with disseminated intravascular coagulation (DIC).

The anticoagulant drugs warfarin and heparin are used to prevent thromboembolic disorders, such as deep vein thrombosis and pulmonary embolism. Warfarin acts by decreasing prothrombin and other procoagulation factors. It alters vitamin K in a manner that reduces its ability to participate in synthesis of the vitamin K–dependent coagulation factors in the liver. Warfarin is readily absorbed after oral administration. Its maximum effect takes 36 to 72 hours because of the varying half-lives of preformed clotting factors that remain in the circulation. Heparin is naturally formed and released in small amounts by mast cells in connective tissue surrounding capillaries. Pharmacologic preparations of heparin are extracted from animal tissues. Heparin binds to antithrombin III, causing a conformational change that increases the ability of antithrombin III to inactivate thrombin, factor Xa, and other clotting factors. By promoting the inactivation of clotting factors, heparin ultimately suppresses the formation of fibrin. Heparin is unable to cross the membranes of the gastrointestinal tract and must be given by injection, usually by intravenous infusion. Low molecular weight heparins have been developed that inhibit activation of factor X, but have little effect on thrombin and other coagulation factors. The low molecular weight heparins are given by subcutaneous injection and require less frequent administration and monitoring compared with the standard (unfractionated) heparin.

There are many potential complications to using warfarin. In addition, the person needs to have frequent laboratory testing of their anticoagulant time with an International Normalized Ratio (INR) test.⁸ A new oral anticoagulant that has less complications and needs less management is dabigatran and is gradually being used with people who have atrial fibrillation. The Centers for Disease Control (2010) estimated that by 2050, 12 million people will have atrial fibrillation. Therefore, the introduction of dabigatran is timely.¹⁰ Furthermore, Freeman (2010) researched the cost of using dabigatran versus warfarin and found dabigatran to be more cost-effective when used for people with atrial fibrillation.¹¹

**Clot Retraction**

Clot retraction normally occurs within 20 to 60 minutes after a clot has formed, contributing to hemostasis by squeezing serum from the clot and joining the edges of the broken vessel.¹ Platelets, through the action of their actin and myosin filaments, also contribute to clot retraction and hemostasis. Clot retraction requires large numbers of platelets, and failure of clot retraction is indicative of a low platelet count.

**Clot Dissolution**

The dissolution of a blood clot begins shortly after its formation. This allows blood flow to be reestablished and permanent tissue repair to take place. The process by which a blood clot dissolves is called fibrinolysis. As with clot formation, clot dissolution requires a sequence of steps controlled by activators and inhibitors. Plasminogen, the proenzyme for the fibrinolytic process, normally is present in the blood in its inactive form. It is converted into its active form, plasmin, by plasminogen activators formed in the vascular endothelium, liver, and kidneys. The plasmin formed from plasminogen digests the fibrin strands of the clot and certain clotting factors, such as fibrinogen, factor V, factor VIII, prothrombin, and factor XII. Circulating plasmin is rapidly inactivated by α₂-plasmin inhibitor, which limits the fibrinolytic process to the local clot and prevents it from occurring in the entire circulation.

Two naturally occurring plasminogen activators are tissue-type plasminogen activator and urokinase-type plasminogen activator. The liver, plasma, and vascular endothelium are the major sources of physiologic activators. These activators are released in response to a number of stimuli, including vasoactive drugs, venous occlusion, elevated body temperature, and exercise. The activators are unstable and rapidly inactivated by inhibitors synthesized by the endothelium and the liver. For this reason, chronic liver disease may cause altered fibrinolytic activity. A major inhibitor, plasminogen activator inhibitor-1, in high concentrations has been associated with deep vein thrombosis, coronary artery disease, and myocardial infarction.¹ Several tissue plasminogen activators (alteplase, reteplase, tenecteplase), produced by recombinant DNA technology, are available for use in treatment of acute myocardial infarction, acute ischemic stroke, and pulmonary embolism.
Understanding Hemostasis

Hemostasis, which refers to the stoppage of blood flow, is divided into three stages:

1. Vessel vasoconstriction
2. Formation of the platelet plug
3. Development of a blood clot as a result of the coagulation process

Clot retraction and clot dissolution are also significant to hemostasis. The process involves the interaction of substrates, enzymes, protein cofactors, and calcium ions that circulate in the blood or are released from platelets and cells in the vessel wall.

Vessel Vasoconstriction

Injury to a blood vessel causes vascular smooth muscle in the vessel wall to contract. This instantaneously reduces the flow of blood from the vessel rupture. Both local nervous reflexes and local humoral factors such as TXA₂, which is released from platelets, contribute to the vasoconstriction.

Formation of the Platelet Plug

Seconds after vessel injury, vWF, released from the endothelium, binds to platelet receptors, causing adhesion of the platelets to the exposed collagen fibers (inset). As the platelets adhere to the collagen fibers on the damaged vessel wall, they become activated and release ADP and TXA₂. The ADP and TXA₂ attract additional platelets, leading to platelet aggregation.
Blood Coagulation

Blood coagulation is a complex process involving the sequential activation of various factors in the blood. There are two coagulation pathways: (1) the intrinsic pathway begins in the circulation and is initiated by activation of circulating factor XII and (2) the extrinsic pathway, which is activated by a cellular lipoprotein called tissue factor that becomes exposed when tissues are injured. Both pathways lead to the activation of factor X, the conversion of prothrombin to thrombin, and conversion of fibrinogen to the insoluble fibrin threads that hold the clot together.

Additionally, the two following processes occur which allow for dissolution of the newly formed clot.

Clot Retraction

Within a few minutes after a clot is formed, the actin and myosin in the platelets that are trapped in the clot begin to contract in a manner similar to that in muscles. As a result, the fibrin strands of the clot are pulled toward the platelets, thereby squeezing serum (plasma without fibrinogen) from the clot and causing it to shrink.

Clot Dissolution or Lysis

Clot dissolution begins shortly after a clot is formed. It begins with activation of plasminogen, an inactive precursor of the proteolytic enzyme, plasmin. When a clot is formed, large amounts of plasminogen are trapped in the clot. The slow release of a very powerful activator called tissue plasminogen activator (t-PA) from injured tissues and vascular endothelium converts plasminogen to plasmin, which digests the fibrin strands, causing the clot to dissolve.
Hemostasis is designed to maintain the integrity of the vascular compartment. The process is divided into three phases—vessel vasoconstriction, which constricts the size of the vessel and reduces blood flow; platelet adherence and formation of the platelet plug; and formation of the fibrin clot, which cements the platelet plug together. Clot retraction, which pulls the edges of the injured vessel together, and clot dissolution, which involves the action of plasmin to dissolve the clot and allow blood flow to be reestablished and tissue healing to take place, are also important processes of hemostasis. Blood coagulation requires the stepwise activation of coagulation factors, carefully controlled by activators and inhibitors.

**IN SUMMARY**

Hypercoagulability represents an exaggerated form of hemostasis that predisposes to thrombosis and blood vessel occlusion. There are two general forms of hypercoagulability states—conditions that create increased platelet function and conditions that cause accelerated activity of the coagulation system. Chart 26.1 summarizes conditions commonly associated with hypercoagulability states. Arterial thrombi are usually due to turbulence and composed largely of platelet aggregates. On the other hand, venous thrombi are usually due to stasis of flow and composed largely of platelet aggregates and fibrin complexes that result from activation of the coagulation cascade.

**Hypercoagulability Associated with Increased Platelet Function**

Hypercoagulability due to increased platelet function results in platelet adhesion, formation of platelet clots, and disruption of blood flow. The causes of increased platelet function are disturbances in flow, endothelial damage, and increased sensitivity of platelets to factors that cause adhesiveness and aggregation. Atherosclerotic plaques disturb blood flow, causing endothelial damage and promoting platelet adherence. Platelets that adhere to the vessel wall release growth factors, which cause proliferation of smooth muscle and thereby contribute to the development of atherosclerosis. Smoking, elevated levels of blood lipids and cholesterol, hemodynamic stress, and diabetes mellitus predispose to vessel damage, platelet adherence, and eventual thrombosis.

**Thrombocytosis**

The term *thrombocytosis* is used to describe elevations in the platelet count above 1,000,000/µL. Thrombocytosis can occur as a reactive process (secondary thrombocytosis) or as an essential process (primary thrombocytosis).

**Etiology and Pathogenesis.** Thrombopoietin is the key hormone in the regulation of megakaryocyte differentiation and platelet formation, although various cytokines (e.g., interleukin-6 and interleukin-11) may also play a role. Megakaryocytes and their platelet progeny have receptors for thrombopoietin. Thrombopoietin is carried in the plasma attached to receptors on the surface of circulating platelets and in an unbound form that is free to promote megakaryocyte proliferation. When the platelet count falls, more unbound thrombopoietin is available to stimulate megakaryocyte proliferation, and when the platelet count rises, less thrombopoietin is available to stimulate proliferation. Thus, megakaryocyte proliferation and platelet production are normally controlled in a negative feedback mechanism by the platelet count.

The most common cause of secondary thrombocytosis is a disease state that stimulates thrombopoietin production. The result is increased megakaryocyte proliferation and platelet production. However, the platelet count seldom exceeds 1,000,000/µL. The common underlying causes of secondary thrombocytosis include tissue damage due to surgery, infection, cancer, and chronic inflammatory conditions such as rheumatoid arthritis and Crohn disease. Usually the only clinically apparent signs are those of the underlying disease. Thrombocytosis may also occur in other myeloproliferative disorders such as polycythemia vera and myelogenous leukemia.

**Hypertension and Other Conditions that Cause Increased Platelet Function**

- Atherosclerosis
- Diabetes mellitus
- Smoking
- Elevated blood lipid and cholesterol levels
- Increased platelet levels

**Accelerated Activity of the Clotting System**

- Pregnancy and the puerperium
- Use of oral contraceptives
- Postsurgical state
- Immobility
- Congestive heart failure
- Malignant diseases

**IN SUMMARY**

Hemostasis is designed to maintain the integrity of the vascular compartment. The process is divided into three phases—vessel vasoconstriction, which constricts the size of the vessel and reduces blood flow; platelet adherence and formation of the platelet plug; and formation of the fibrin clot, which cements the platelet plug together. Clot retraction, which pulls the edges of the injured vessel together, and clot dissolution, which involves the action of plasmin to dissolve the clot and allow blood flow to be reestablished and tissue healing to take place, are also important processes of hemostasis. Blood coagulation requires the stepwise activation of coagulation factors, carefully controlled by activators and inhibitors.

**HYPERCOAGULABILITY STATES**

After completing this section of the chapter, you should be able to meet the following objectives:

- Compare normal and abnormal clotting.
- Describe the causes and effects of increased platelet function.
- State two conditions that contribute to increased clotting activity.

Hypercoagulability represents an exaggerated form of hemostasis that predisposes to thrombosis and blood vessel occlusion. There are two general forms of hypercoagulability states—conditions that create increased platelet function and conditions that cause accelerated activity of the coagulation system. Chart 26.1 summarizes conditions commonly associated with hypercoagulability states. Arterial thrombi are usually due to turbulence and composed largely of platelet aggregates. On the other hand, venous thrombi are usually due to stasis of flow and composed largely of platelet aggregates and fibrin complexes that result from activation of the coagulation cascade.

**Hypercoagulability Associated with Increased Platelet Function**

Hypercoagulability due to increased platelet function results in platelet adhesion, formation of platelet clots, and disruption of blood flow. The causes of increased platelet function are disturbances in flow, endothelial damage, and increased sensitivity of platelets to factors that cause adhesiveness and aggregation. Atherosclerotic plaques disturb blood flow, causing endothelial damage and promoting platelet adherence. Platelets that adhere to the vessel wall release growth factors, which cause proliferation of smooth muscle and thereby contribute to the development of atherosclerosis. Smoking, elevated levels of blood lipids and cholesterol, hemodynamic stress, and diabetes mellitus predispose to vessel damage, platelet adherence, and eventual thrombosis.

**Thrombocytosis**

The term *thrombocytosis* is used to describe elevations in the platelet count above 1,000,000/µL. Thrombocytosis can occur as a reactive process (secondary thrombocytosis) or as an essential process (primary thrombocytosis).

**Etiology and Pathogenesis.** Thrombopoietin is the key hormone in the regulation of megakaryocyte differentiation and platelet formation, although various cytokines (e.g., interleukin-6 and interleukin-11) may also play a role. Megakaryocytes and their platelet progeny have receptors for thrombopoietin. Thrombopoietin is carried in the plasma attached to receptors on the surface of circulating platelets and in an unbound form that is free to promote megakaryocyte proliferation. When the platelet count falls, more unbound thrombopoietin is available to stimulate megakaryocyte proliferation, and when the platelet count rises, less thrombopoietin is available to stimulate proliferation. Thus, megakaryocyte proliferation and platelet production are normally controlled in a negative feedback mechanism by the platelet count.

The most common cause of secondary thrombocytosis is a disease state that stimulates thrombopoietin production. The result is increased megakaryocyte proliferation and platelet production. However, the platelet count seldom exceeds 1,000,000/µL. The common underlying causes of secondary thrombocytosis include tissue damage due to surgery, infection, cancer, and chronic inflammatory conditions such as rheumatoid arthritis and Crohn disease. Usually the only clinically apparent signs are those of the underlying disease. Thrombocytosis may also occur in other myeloproliferative disorders such as polycythemia vera and myelogenous leukemia.
Primary or essential thrombocytosis represents a myeloproliferative (bone marrow) disorder of the hematopoietic stem cells. Although thrombopoietin levels are often normal in essential thrombocytosis, abnormalities in the thrombopoietin receptor and platelet binding cause higher-than-expected levels of free thrombopoietin. This leads to increased megakaryocyte proliferation and platelet production. Dysfunction of the platelets produced contributes to the major clinical features of bleeding and thrombosis.

Clinical Manifestations and Treatment. The common clinical manifestations of essential thrombocytoesis are thrombosis and hemorrhage. Thrombotic events include deep vein thrombosis and pulmonary embolism and portal and hepatic vein thrombosis. Some people experience erythromelalgia, a painful throbbing and burning of the fingers caused by occlusion of the arterioles by platelet aggregates. Typically, the disorder is characterized by long asymptomatic periods punctuated by occasional thrombotic episodes and hemorrhagic crises, both of which occur in people with very high platelet counts. Treatment includes the use of platelet-lowering drugs (e.g., hydroxyurea) in high-risk cases. Aspirin may be a highly effective adjunctive therapy in people with recurrent thrombotic complications.

Hypercoagulability Associated with Increased Clotting Activity
Thrombus formation due to activation of the coagulation system can result from primary (genetic) or secondary (acquired) disorders affecting the coagulation components of the blood clotting process (i.e., an increase in procoagulation factors or a decrease in anticoagulation factors).

Inherited Disorders
Of the inherited causes of hypercoagulability, mutations in the factor V gene and prothrombin gene are the most common. Approximately 2% to 15% of white people carry a specific factor V mutation (referred to as the Leiden mutation, because of the Dutch city where it was first discovered). In people with inherited defects in factor V, the mutant factor Va cannot be inactivated by protein C. As a result, an important antithrombotic counterregulatory mechanism is lost. The defect predisposes to venous thrombosis. Among people with recurrent deep vein thrombosis, the frequency of the mutation may be as high as 60%.

A single nucleotide change in the prothrombin gene, which affects 1% to 2% of the population, is associated with elevated prothrombin levels and an almost threefold increase in venous thromboses. Less common primary hypercoagulable states include inherited deficiencies of anticoagulants such as antithrombin III, protein C, and protein S. Another hereditary defect results in high circulating levels of homocysteine, which predisposes to venous and arterial thrombosis by activating platelets and altering antithrombotic mechanisms.

Acquired Disorders
Among the acquired or secondary factors that lead to increased coagulation and thrombosis are venous stasis due to prolonged bed rest and immobility, myocardial infarction, cancer, hyperestrogenic states, and oral contraceptives. Smoking and obesity promote hypercoagulability for unknown reasons.

Stasis of blood flow causes accumulation of activated clotting factors and platelets and prevents their interactions with inhibitors. Slow and disturbed flow is a common cause of venous thrombosis in the immobilized or postsurgical person. It is significant to insure all immobilized people are on heparin therapy, if not contraindicated, in order to prevent deep vein thrombosis and pulmonary embolism. Additionally, evidence suggests that intermittent pneumatic compression devices are very helpful in preventing thromboembolic complications with immobility. People with inflammatory bowel disease are at high risk for venous and arterial thromboembolism, but also can suffer adverse effects such as gastrointestinal bleeding if anticoagulated. Therefore, it is important that factors that promote thrombotic effects be minimized such as inflammation, steroid therapy, hospitalization, oral contraceptives, deficiency in B vitamins and folate, smoking, and use of central intravenous catheters so that minimal or no anticoagulation is necessary. Heart failure also contributes to venous congestion and thrombosis. Hyperviscosity syndromes (polycythemia) and deformed red blood cells in sickle cell disease increase the resistance to flow and cause small-vessel stasis.

The incidence of stroke, thromboemboli, and myocardial infarction is greater in women who use oral contraceptives, particularly those older than 35 years of age and those who are heavy smokers. Clotting factors are also increased during normal pregnancy. These changes, along with limited activity during the puerperium (immediate postpartum period), predispose to venous thrombosis.

Hypercoagulability also is common in cancer and sepsis. Many tumor cells are thought to release tissue factor molecules, which, along with the increased immobility and sepsis seen in people with malignant disease, contribute to thrombosis in these people.

Antiphospholipid Syndrome
Another cause of increased venous and arterial thrombosis is the antiphospholipid syndrome. This condition is associated with autoantibodies (primarily immunoglobulin G [IgG]) directed
against protein-binding phospholipids, which results in increased coagulation activity.\(^\text{15}\) The common features of antiphospholipid syndrome are venous and arterial thrombi, recurrent fetal loss, and thrombocytopenia. The disorder can be a primary condition occurring in isolation with signs of hypercoagulability or a secondary condition sometimes associated with systemic lupus erythematosus.\(^\text{4}\)

**Etiology and Pathogenesis.** Although the mechanisms for this syndrome are unknown, several potential pathways have been identified:

- The antibodies may interfere with the coagulation cascade, leading to a hypercoagulability state.
- The antibodies may directly bind to the endothelial cell surface, causing secretion of cytokines that result in activation and aggregation of platelets.
- The antibodies may target a serum phospholipid-binding protein that functions as an anticoagulant.

In addition to the action of the antibodies, it seems likely that other factors play a role in determining whether a person develops clinical manifestations of the disorder. Although speculative, these factors may include vascular trauma or the presence of infection that leads to cytokine production and endothelial cell activation.\(^\text{4}\)

**Clinical Manifestations.** People with the disorder present with a variety of clinical manifestations, typically those characterized by recurrent venous and arterial thrombi. Cardiac valvular vegetations associated with adherence of thrombi and thrombocytopenia due to excessive platelet consumption may also occur. Venous thrombosis, especially in the deep leg veins, occurs in up to 50% of people with the syndrome, half of whom develop pulmonary emboli. Arterial thrombosis involves the brain in up to 50% of cases, causing transient ischemic attacks or strokes.\(^\text{15}\) Other sites for arterial thrombosis are the coronary arteries of the heart and the retinal, renal, and peripheral arteries. Women with the disorder commonly have a history of recurrent pregnancy losses because of ischemia and thrombosis of the placental vessels. These women also have increased risk of giving birth to a premature infant owing to pregnancy-associated hypertension and uteroplacental insufficiency.

In most people with antiphospholipid syndrome, the thrombotic events occur as a single episode at one anatomic site. In some people, recurrences may occur months or years later and mimic the initial event. Occasionally, someone may present with multiple vascular occlusions involving many organ systems. This rapid onset condition is termed *catastrophic antiphospholipid syndrome* and is associated with a high mortality rate.\(^\text{16}\)

**Treatment.** Treatment of the syndrome focuses on removal or reduction in factors that predispose to thrombosis, including advice to stop smoking and counseling against use of estrogen-containing oral contraceptives by women.

The acute thrombotic event is treated with anticoagulants (heparin and warfarin) and immune suppression in refractory cases. Aspirin and anticoagulant drugs may be used to prevent future thrombosis.\(^\text{15}\)

**IN SUMMARY**

Hypercoagulability causes excessive clotting and contributes to thrombus formation. It results from conditions that foster an increase in platelet numbers or function or accelerated activity of the coagulation system. Thrombocytosis, an elevation in the platelet count, can occur as a reactive process (secondary thrombocytosis) or an essential process (primary thrombocytosis). Increased platelet function usually results from disorders such as atherosclerosis that damage the vascular endothelium and disturb blood flow or from conditions such as smoking that increase sensitivity of platelets to factors that promote adhesiveness and aggregation.

Factors that cause accelerated activity of the coagulation system include blood flow stasis, resulting in an accumulation of coagulation factors, and alterations in the components of the coagulation system (*i.e.*, an increase in procoagulation factors or a decrease in anticoagulation factors). The antiphospholipid syndrome, an acquired venous and arterial clotting disorder, manifests as a primary disorder or can be a secondary disorder associated with systemic lupus erythematosus. It is associated with antiphospholipid antibodies, which promote thrombosis that can affect many organs.

**BLEEDING DISORDERS**

After completing this section of the chapter, you should be able to meet the following objectives:

- Differentiate the mechanisms of drug-induced thrombocytopenia and idiopathic thrombocytopenia.
- Describe the manifestations of thrombocytopenia.
- State three common defects of coagulation factors and their etiologies.
- Differentiate between the mechanisms of bleeding in hemophilia A and von Willebrand disease.
- Describe the effect of vascular disorders on hemostasis.
- Explain the physiologic basis of acute disseminated intravascular coagulation.

Bleeding disorders or impairment of blood coagulation can result from defects in any of the factors that contribute to hemostasis. Bleeding can occur as a result of disorders associated with platelet number or function, coagulation factors, and blood vessel integrity.
Bleeding Associated with Platelet Disorders

Bleeding due to platelet disorders reflects a decrease in platelet number due to decreased production, increased destruction, or impaired function of platelets. Spontaneous bleeding from platelet disorders most often involves small vessels of the mucous membranes and skin. Common sites of bleeding are the mucous membranes of the nose, mouth, gastrointestinal tract, and uterine cavity. Cutaneous bleeding is seen as pinpoint hemorrhages (petechiae) and purple areas of bruising (purpura) in dependent areas where the capillary pressure is higher (Fig. 26.4). Petechiae are seen almost exclusively in conditions of platelet deficiency and not platelet dysfunction. Bleeding of the intracranial vessels is a rare danger with severe platelet depletion.

Thrombocytopenia

A reduction in platelet number, also referred to as thrombocytopenia, is an important cause of generalized bleeding. Thrombocytopenia usually refers to a decrease in the number of circulating platelets to a level less than 150,000/µL. The greater the decrease in the platelet count, the greater the risk of bleeding. Thrombocytopenia can result from a decrease in platelet production, increased sequestration of platelets in the spleen, or decreased platelet survival.

Decreased platelet production due to loss of bone marrow function occurs in aplastic anemia. Replacement of bone marrow by malignant cells, such as that occurring in leukemia, also results in decreased production of platelets. Radiation therapy and drugs such as those used in the treatment of cancer may depress bone marrow function and reduce platelet production. Infection with human immunodeficiency virus (HIV) or cytomegalovirus may suppress the production of megakaryocytes, the platelet precursors.

Production of platelets may be normal, but excessive pooling of platelets in the spleen may occur. Although the spleen normally sequesters 30% to 40% of the platelets before release into the circulation, the proportion can be as great as 90% when the spleen is enlarged in splenomegaly. When necessary, hypersplenic thrombocytopenia may be treated with splenectomy.

Reduced platelet survival is caused by a variety of immune and nonimmune mechanisms. Platelet destruction may be caused by antiplatelet antibodies. The antibodies may be directed against platelet self-antigens or against antigens on the platelets from blood transfusions or pregnancy. The antibodies target the platelet membrane glycoproteins GPIIb/IIIa and GPIb/IX. Nonimmune destruction of platelets results from mechanical injury due to prosthetic heart valves or malignant hypertension, which results in small-vessel narrowing. In acute DIC or thrombotic thrombocytopenic purpura, excessive platelet consumption leads to a deficiency.

Drug-Induced Thrombocytopenia. Some drugs, such as quinine, quinidine, and certain sulfa-containing antibiotics, may induce thrombocytopenia. These drugs induce an antigen–antibody response and formation of immune complexes that cause platelet destruction by complement-mediated lysis. In people with drug-associated thrombocytopenia, there is a rapid fall in the platelet count within 2 to 3 days of resuming a drug or 7 or more days (i.e., the time needed to mount an immune response) after starting a drug for the first time. The platelet count rises rapidly after the drug is discontinued.

Heparin-Induced Thrombocytopenia. Heparin-induced thrombocytopenia (HIT) is associated with the anticoagulant drug heparin. Ten percent of people treated with heparin develop a mild, transient thrombocytopenia within 2 to 5 days of starting the drug. However, approximately 1% to 5% of people treated with heparin experience life-threatening thromboembolic events 1 to 2 weeks after the start of therapy. HIT is caused by an immune reaction directed against a complex of heparin and platelet factor 4, a normal component of platelet granules that binds tightly to heparin. The binding of antibody to platelet factor 4 produces immune complexes that activate the remaining platelets, leading to thrombosis. In addition, prothrombotic platelet particles and induction of tissue factor continue to promote coagulation.

The treatment of HIT requires the immediate discontinuation of heparin therapy and the use of alternative anticoagulants to prevent thrombosis recurrence. The newer low molecular weight heparin has been shown to be effective in reducing the incidence of heparin-induced complications compared with the older, high molecular weight form of the drug.

Immune Thrombocytopenic Purpura. Immune thrombocytopenic purpura (ITP), an autoimmune disorder, results in platelet antibody formation and excess destruction of
platelets. The disorder can occur in the absence of any known risk factors (primary or idiopathic ITP) or as a secondary disorder due to an underlying disorder and as an acute (duration of 6 months or less) or chronic disorder. Secondary forms of ITP may be associated with acquired immunodeficiency syndrome (AIDS), systemic lupus erythematosus, antiphospholipid syndrome, chronic lymphocytic leukemia, lymphoma, hepatitis C, and drugs such as heparin and quinidine.

An acute ITP disorder occurs in young children (5 years of age) and usually follows a viral infection. It is characterized by sudden onset of petechiae and purpura and is usually a self-limited disorder requiring no treatment. Most children recover in a few weeks. In contrast, primary ITP is often a chronic disorder in adults with an insidious onset that seldom follows an infection.

**Etiology and Pathogenesis.** The thrombocytopenia that occurs in ITP is thought to result from multiple mechanisms, including antiplatelet antibodies against glycoproteins (IIb/IIIa and IIb/IX) in the platelet membrane. The platelets, which are made more susceptible to phagocytosis because of the antibody, are destroyed in the spleen. Plasma levels of thrombopoietin, the major factor that stimulates growth and development of megakaryocytes, are not elevated in people with ITP. Evidence suggests that ITP is caused by T-cell dysfunction, specifically CD4 and T regulatory cells, which trigger the autoimmune response and proceed to thrombocytopenia.

**Clinical Manifestations.** Manifestations of ITP include a history of bruising, bleeding from gums, epistaxis (i.e., nosebleed), melena, and abnormal menstrual bleeding in those with moderately reduced platelet counts. Because the spleen is the site of platelet destruction, splenic enlargement may occur. The condition may be discovered incidentally or as a result of signs of bleeding, often into the skin (i.e., purpura and petechiae) or oral mucosa.

**Diagnosis and Treatment.** Diagnosis of ITP usually is based on severe thrombocytopenia (platelet counts <20,000 to 30,000/µL) and exclusion of other causes. Tests for the platelet-bound antibodies are available but lack specificity (e.g., they react with platelet antibodies from other sources). The secondary form of ITP sometimes mimics the idiopathic form of the disorder; therefore, the diagnosis is made only after excluding other known causes of thrombocytopenia.

The decision to treat ITP is based on the platelet count and the degree of bleeding. Many persons with ITP do well without treatment. Corticosteroids are usually used as initial therapy. Other effective initial treatments include intravenous immune globulin. However, this treatment is expensive, and the beneficial effect lasts only 1 to 2 weeks.

**Thrombotic Thrombocytopenic Purpura.** Thrombotic thrombocytopenic purpura (TTP) is a combination of thrombocytopenia, hemolytic anemia, renal failure, fever, and neurologic abnormalities. It is a rare disorder that likely results from introduction of platelet-aggregating substances into the circulation. The underlying cause of many cases is the deficiency of an enzyme (designated ADAMTS 13) that degrades large molecular weight multimers of vWF, allowing them to accumulate and cause platelet aggregation and adhesion to the endothelium.

**Etiology and Pathogenesis.** The enzyme deficiency may be inherited or acquired as a result of antibody directed against the enzyme. TTP usually occurs in previously healthy people, but may be associated with autoimmune collagen diseases, drugs, infections such as HIV, and pregnancy. The disorder is similar to DIC but does not involve the clotting system. Toxins produced by some strains of *Escherichia coli* (e.g., *E. coli* O157:H7) cause endothelial injury and are responsible for a similar condition, hemolytic uremic syndrome (HUS).

The onset of TTP is abrupt and the outcome may be fatal. Widespread vascular occlusions result from thrombi in the arterioles and capillaries of many organs, including the heart, brain, and kidneys. Erythrocytes become fragmented as they circulate through the partly occluded vessels, causing hemolytic anemia and jaundice.

**Clinical Manifestations and Treatment.** The clinical manifestations include purpura, petechiae, vaginal bleeding, and neurologic symptoms ranging from headache to seizures and altered consciousness. Emergency treatment for TTP includes plasmapheresis, a procedure that involves removal of plasma from withdrawn blood and replacement with fresh-frozen plasma. Plasma infusion provides the deficient enzyme. With plasmapheresis and plasma infusion treatment, there is a complete recovery in 80% of cases.

**Impaired Platelet Function**

Impaired platelet function (also called thrombocytopathia) may result from inherited disorders of adhesion (e.g., von Willebrand disease) or acquired defects caused by drugs, disease, or surgery involving extracorporeal circulation (i.e., cardiopulmonary bypass). Defective platelet function is also common in uremia, presumably because of unexcreted waste products.

The use of aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs) is the most common cause of impaired platelet function. Aspirin produces irreversible acetylation of platelet cyclooxygenase activity and consequently the synthesis of TXA₂, which is required for platelet aggregation. In contrast to the effects of aspirin, the inhibition of cyclooxygenase by other NSAIDs is reversible and lasts only for the duration of drug action. Aspirin (81 mg daily) commonly is used to prevent formation of arterial thrombi and reduce the risk for heart attack and stroke. Chart 26.2 lists other drugs that impair platelet function.
BLEEDING DISORDERS

Disorders of platelet plug formation include a decrease in platelet numbers due to inadequate platelet production (bone marrow dysfunction), excess platelet destruction (thrombocytopenia), abnormal platelet function (thrombocytopathia), or defects in vWF. Impairment of the coagulation stage of hemostasis is caused by a deficiency in one or more of the clotting factors. Disorders of blood vessel integrity result from structurally weak vessels or vessel damage due to inflammation and immune mechanisms.

Blood coagulation defects can result from deficiencies or impaired function of one or more of the clotting factors, including vWF. Deficiencies can arise because of inherited disease or defective synthesis or increased consumption of the clotting factors. Bleeding resulting from clotting factor deficiencies typically occurs after injury or trauma. Large bruises, hematomas, and prolonged bleeding into the gastrointestinal or urinary tracts or joints are common.

**Inherited Disorders**

Von Willebrand disease and hemophilia (A and B) are two of the most common inherited disorders of bleeding. Von Willebrand disease is considered the most frequent inherited coagulopathy and affects approximately 1% to 2% of the population. Hemophilia A (factor VIII deficiency) affects 1 in 5000 male live births. Hemophilia B (factor IX deficiency) occurs in approximately 1 in 20,000 people, accounting for 15% of people with hemophilia. It is genetically and clinically similar to hemophilia A. Von Willebrand disease and hemophilia A are caused by defects involving the factor VIII–vWF complex. vWF, which is synthesized by the endothelium and megakaryocytes, is required for platelet adhesion to the subendothelial matrix of the blood vessel. It also serves as the carrier for factor VIII and is important for the stability of factor VIII in the circulation by preventing its proteolysis. Factor VIII coagulant protein, the functional portion, is produced by the liver and endothelial cells. Thus, factor VIII and vWF, synthesized separately, come together and circulate in the plasma as a unit that serves to promote clotting and adhesion of platelets to the vessel wall.

**Von Willebrand Disease.** Von Willebrand disease is a relatively common hereditary bleeding disorder characterized by a deficiency or defect in vWF. As many as 20 variants of von Willebrand disease have been described. These variants can be grouped into two categories—types 1 and 3, which are associated with reduced levels of vWF, and type 2, which is characterized by defects in vWF.

**Classification.** Type 1, an autosomal dominant disorder, accounts for approximately 70% of cases and is relatively mild. Type 2, also an autosomal dominant disorder, accounts for about 25% of cases and is associated with mild to moderate bleeding. Type 3, which is a relatively rare autosomal recessive disorder, is associated with extremely low levels of functional vWF and correspondingly severe clinical manifestations. People with von Willebrand disease have a compound defect involving platelet function and the coagulation pathway.

**Clinical Manifestations.** Clinical manifestations include spontaneous bleeding from the nose, mouth, and gastrointestinal tract, excessive menstrual flow, and a prolonged bleeding time in the presence of a normal platelet count. Most cases (i.e., types 1 and 2) are mild and require no treatment, and many people with the disorder are diagnosed when surgery or dental extraction results in prolonged bleeding. In severe cases

*This list is not intended to be inclusive.*
(i.e., type 3), life-threatening gastrointestinal bleeding and joint hemorrhage may be similar to that seen in hemophilia. The bleeding associated with von Willebrand disease is usually mild, and no treatment is routinely administered other than avoidance of aspirin.

Hemophilia A. Hemophilia A is an X-linked recessive disorder that primarily affects males. Although it is a hereditary disorder, there is no family history of the disorder in approximately 30% of newly diagnosed cases, suggesting that it has arisen as a new mutation in the factor VIII gene. Approximately 90% of people with hemophilia produce insufficient quantities of the factor, and 10% produce a defective form. The percentage of normal factor VIII activity in the circulation depends on the genetic defect and determines the severity of hemophilia (i.e., 6% to 30% in mild hemophilia, 2% to 5% in moderate hemophilia, and 1% or less in severe forms of hemophilia). In mild or moderate forms of the disease, bleeding usually does not occur unless there is a local lesion or trauma such as surgery or a dental procedure. The mild disorder may not be detected in childhood. In severe hemophilia, bleeding usually occurs in childhood (e.g., it may be noticed at the time of circumcision) and is spontaneous and severe, often occurring several times a month.

Clinical Manifestations. Characteristically, bleeding occurs in soft tissues, the gastrointestinal tract, and the hip, knee, elbow, and ankle joints. Spontaneous joint bleeding usually begins when a child begins to walk. Often, a target joint is prone to repeated bleeding. The bleeding causes inflammation of the synovium, with acute pain and swelling. Without proper treatment, chronic bleeding and inflammation cause joint fibrosis and contractures, resulting in major disability.

Treatment. The prevention of trauma is important in people with hemophilia. Aspirin and other NSAIDs that affect platelet function should be avoided. Factor VIII replacement therapy administered at home has reduced the typical musculoskeletal damage. It is initiated when bleeding occurs or as prophylaxis with repeated bleeding episodes. The recombinant products and continuous infusion pumps may allow prevention rather than therapy for hemorrhage. The development of inhibitory antibodies to recombinant factor VIII is still a major complication of treatment.

The cloning of the factor VIII gene and progress in gene delivery systems have led to the hope that hemophilia A may be cured by gene replacement therapy. Carrier detection and prenatal diagnosis can now be done by analysis of direct gene mutation or DNA linkage studies. Prenatal amniocentesis or chorionic villus sampling is used to predict complications and determine therapy. It may eventually be used to select patients for gene addition.

Acquired Disorders

Coagulation factors V, VII, IX, X, XI, and XII, prothrombin, and fibrinogen are synthesized in the liver. In liver disease, synthesis of these clotting factors is reduced, and bleeding may result. Of the coagulation factors synthesized in the liver, factors II, VII, IX, and X and prothrombin require the presence of vitamin K for normal activity. In vitamin K deficiency, the liver produces the clotting factor, but in an inactive form. Vitamin K is a fat-soluble vitamin that is continuously being synthesized by intestinal bacteria. This means that a deficiency in vitamin K is not likely to occur unless intestinal synthesis is interrupted or absorption of the vitamin is impaired. Vitamin K deficiency can occur in the newborn infant before the establishment of the intestinal flora. It can also occur as a result of treatment with broad-spectrum antibiotics that destroy intestinal flora. Because vitamin K is a fat-soluble vitamin, its absorption requires bile salts. Vitamin K deficiency may result from impaired fat absorption caused by liver or gallbladder disease.

Bleeding Associated with Vascular Disorders

Bleeding resulting from vascular disorders is sometimes referred to as nonthrombocytopenic purpura. These disorders may occur because of structurally weak vessel walls or because of damage to vessels by inflammation or immune responses. Most often they are characterized by easy bruising and the spontaneous appearance of petechiae and purpura of the skin and mucous membranes. In people with bleeding disorders caused by vascular defects, the platelet count and results of other tests for coagulation factors are normal.

Among the vascular disorders that cause bleeding are hemorrhagic telangiectasia, an uncommon autosomal dominant disorder characterized by thin-walled, dilated capillaries and arterioles; vitamin C deficiency (i.e., scurvy), resulting in poor collagen synthesis and failure of the endothelial cells to be cemented together properly, which causes a fragile vascular wall; Cushing disease, causing protein wasting and loss of vessel tissue support because of excess cortisol; and senile purpura (i.e., bruising in elderly persons), caused by impaired collagen synthesis in the aging process. Vascular defects also occur in the course of DIC or as a result of microthrombi and corticosteroid therapy.

Disseminated Intravascular Coagulation

DIC is a paradox in the hemostatic sequence and is characterized by widespread coagulation and bleeding in the vascular compartment. It is not a primary disease but occurs as a complication of a wide variety of conditions. DIC begins with massive activation of the coagulation sequence as a result of unregulated generation of thrombin, resulting in systemic formation of fibrin. In addition, levels of all the major anticoagulants are reduced (Fig. 26.5). The microthrombi that result cause vessel occlusion and tissue ischemia. Multiple organ failure may ensue. Clot formation consumes all available coagulation proteins and platelets, and severe hemorrhage results.
Etiology and Pathogenesis

The disorder can be initiated by activation of the intrinsic or extrinsic pathway, or both. Activation through the extrinsic pathway occurs with liberation of tissue factors and is associated with obstetric complications, trauma, bacterial sepsis, and cancers.

The intrinsic pathway may be activated through extensive endothelial damage, with activation of factor XII. Endothelial damage may be caused by viruses, infections, immune mechanisms, stasis of blood, or temperature extremes.

Impaired anticoagulation pathways are also associated with reduced levels of antithrombin and the protein C anticoagulant system in DIC. There is evidence that the underlying cause of DIC is infection or inflammation and the cytokines (tumor necrosis factor, interleukin-1, and others) liberated in the process are the pivotal mediators. These cytokines not only mediate inflammation but also can increase the expression of tissue factor on endothelial cells and simultaneously decrease the expression of thrombomodulin. Thrombomodulin, a glycoprotein that is present on the cell membrane of endothelial
Chapter 26  Disorders of Hemostasis  663

Clinical Manifestations

Although coagulation and formation of microemboli characterize DIC, its acute manifestations usually are more directly related to the bleeding problems that occur. The bleeding may be present as petechiae, purpura, oozing from puncture sites, or severe hemorrhage.

Uncontrolled postpartum bleeding may indicate DIC. Microemboli may obstruct blood vessels and cause tissue hypoxia and necrotic damage to organ structures, such as the kidneys, heart, lungs, and brain. As a result, common clinical signs may be due to renal, circulatory, or respiratory failure, acute bleeding ulcers, or convulsions and coma. A form of hemolytic anemia may develop as red cells are damaged passing through vessels partially blocked by thrombus.4

Treatment

The treatment of DIC is directed toward managing the primary disease, replacing clotting components, and preventing further activation of clotting mechanisms. Transfusions of fresh-frozen plasma, platelets, or fibrinogen-containing cryoprecipitate may correct the clotting factor deficiency.

IN SUMMARY

Bleeding disorders or impairment of blood coagulation can result from defects in any of the factors that contribute to hemostasis: platelets, coagulation factors, or vascular integrity. The number of circulating platelets can be decreased (i.e., thrombocytopenia) because of reduced bone marrow production, excess pooling in the spleen, or immune destruction. Impaired platelet function (i.e., thrombocytopenia) is caused by inherited disorders (von Willebrand disease) or results from drugs or disease. Impairment of blood coagulation can result from deficiencies of one or more of the known clotting factors. Deficiencies can arise because of acquired disorders (i.e., liver disease or vitamin K deficiency) or inherited diseases (i.e., hemophilia A or von Willebrand disease). Bleeding may also occur from structurally weak vessels that result from impaired synthesis of vessel wall components (i.e., vitamin C deficiency, excessive cortisol levels as in Cushing disease, or the aging process) or from damage by genetic mechanisms (i.e., hemorrhagic telangiectasia) or the presence of microthrombi.

DIC is characterized by widespread coagulation and bleeding in the vascular compartment. It begins with massive activation of the coagulation cascade and generation of microthrombi that cause vessel occlusion and tissue ischemia. Clot formation consumes all available coagulation proteins and platelets, and severe hemorrhage results.

Although the lungs provide the means for gas exchange between the external and internal environments, it is the hemoglobin in the red blood cells that transports oxygen to the tissues. The red blood cells also function as carriers of carbon dioxide and participate in acid–base balance. The function of the red blood cells, in terms of oxygen transport, is discussed in Chapter 35 and acid–base balance in Chapter 40. This chapter focuses on the red blood cell, blood types and transfusion therapy, anemia, polycythemia, and age-related changes in the red blood cells.

The erythrocytes, 500 to 1000 times more numerous than other blood cells, are the most common type of blood cell. The mature red blood cell, the erythrocyte, is a nonnucleated, biconcave disk (Fig. 27.1A). This unique shape contributes in two ways to the oxygen transport function of the erythrocyte. The biconcave shape provides a larger surface area for oxygen diffusion than would a spherical cell of the same volume, and the thinness of the cell membrane enables oxygen to diffuse rapidly between the exterior and the innermost regions of the cell (Fig. 27.1).

Another structural feature that facilitates the transport function of the red blood cell is the flexibility of its membrane.
predominant hemoglobin in the fetus from the 3rd through the 9th months of gestation. It has a pair of gamma (γ) chains substituted for the α chains. Because of this chain substitution, HbF has a higher affinity for oxygen than HbA. This affinity facilitates the transfer of oxygen across the placenta from the HbA in the mother’s blood to the HbF in the fetus’s blood. HbF is generally replaced within 6 months of birth with HbA.

KEY POINTS

**RED BLOOD CELLS**

- The function of red blood cells, facilitated by the iron-containing hemoglobin molecule, is to transport oxygen from the lungs to the tissues.
- The red blood cell, which has a life span of approximately 120 days, is broken down in the spleen; the degradation products such as iron and amino acids are recycled.

**Hemoglobin Synthesis**

The rate at which hemoglobin is synthesized depends on the availability of iron for heme synthesis. A lack of iron results in relatively small amounts of hemoglobin in the red blood cells. The amount of iron in the body is approximately 2 g in...
Chapter 27 Disorders of Red Blood Cells

...where it is stored as ferritin, a protein–iron complex, which can easily return to the circulation. Serum ferritin levels, which can be measured in the laboratory, provide an index of body iron stores. Clinically, decreased ferritin levels usually indicate the need for prescription of iron supplements such as ferrous sulfate. Transferrin can also deliver iron to the developing red cell in bone marrow by binding to membrane receptors. This iron is taken up by the developing red cell, where it is used in heme synthesis.

Red Cell Production

Erythropoiesis refers to the production of red blood cells. After birth, red cells are produced in the red bone marrow. Until 5 years of age, almost all bones produce red cells to meet the growth needs of a child, after which bone marrow activity gradually declines. After 20 years of age, red cell production takes place mainly in the membranous bones of the vertebrae, sternum, ribs, and pelvis. With this reduction in activity, the red bone marrow is replaced with fatty yellow bone marrow.

The red blood cells are derived from precursor cells called erythroblasts, which are formed continuously from...
the pluripotent stem cells in the bone marrow (Fig. 27.4). The red cell precursors move through a series of divisions, each producing a smaller cell as they continue to develop into mature red blood cells. Hemoglobin synthesis begins at the early erythroblast stage and continues until the cell becomes a mature erythrocyte. During its transformation from normoblast to reticulocyte, the red blood cell accumulates hemoglobin as the nucleus condenses and is finally lost. The period from stem cell to emergence of the reticulocyte in the circulation normally takes approximately 1 week. Maturation of reticulocyte to erythrocyte takes approximately 24 to 48 hours. During this process, the red cell loses its mitochondria and ribosomes, along with its ability to produce hemoglobin and engage in oxidative metabolism. Most maturing red cells enter the blood as reticulocytes. Approximately 1% of the body’s total complement of red blood cells is generated from bone marrow each day, and the reticulocyte count therefore serves as an index of the erythropoietic activity of the bone marrow.

Erythropoiesis is governed for the most part by tissue oxygen needs. Any condition that causes a decrease in the amount of oxygen that is transported in the blood produces an increase in red cell production. The oxygen content of the blood does not act directly on the bone marrow to stimulate red blood cell production. Instead, the decreased oxygen content is sensed by the peritubular cells in the kidneys, which then produce a hormone called erythropoietin. Normally, about 90% of all erythropoietin is produced by the kidneys, with the remaining 10% formed in the liver. Although erythropoietin is the key regulator of erythropoiesis, a number of growth factors, including granulocyte colony–stimulating factor (G-CSF), granulocyte–macrophage (GM)-CSF, and insulin-like growth factor-1 (IGF-1), are involved in the early stages of erythropoiesis.

Erythropoietin acts primarily in later stages of erythropoiesis to induce the erythrocyte colony–forming units to proliferate and mature through the normoblast stage into reticulocytes and mature erythrocytes. In the absence of erythropoietin, as in kidney failure, hypoxia has little or no effect on red blood cell production. Human erythropoietin can be produced by recombinant deoxyribonucleic acid (DNA) technology. It is used for the management of anemia in cases of chronic renal failure, for anemias induced by chemotherapy in persons with malignancies, and in the treatment of anemia in human immunodeficiency virus (HIV)–infected persons.

Because red blood cells are released into the blood as reticulocytes, the percentage of these cells is higher when there is a marked increase in red blood cell production. In some severe forms of anemia, the reticulocytes (normally about 1%) may account for as much as 30% of the total red cell count. In some situations, red cell production is so accelerated that numerous erythroblasts appear in the blood.

**Red Cell Destruction**

Mature red blood cells have a life span of approximately 4 months, or 120 days. As the red blood cell ages, a number of changes occur—metabolic activity in the cell decreases, enzyme activity declines, and adenosine triphosphate (ATP) decreases. Membrane lipids become reduced and the cell membrane becomes more fragile, causing the red cell to self-destruct.
as it passes through narrow places in the circulation and in the small trabecular spaces in the spleen. The rate of red cell destruction (1% per day) normally is equal to the rate of red cell production, but in conditions such as hemolytic anemia, the cell’s life span may be shorter.

The destruction of red blood cells is facilitated by a group of large phagocytic cells found in the spleen, liver, bone marrow, and lymph nodes. These phagocytic cells recognize old and defective red cells and then ingest and destroy them in a series of enzymatic reactions. During these reactions, the amino acids from the globulin chains and iron from the heme units are salvaged and reused (Fig. 27.5). The bulk of the heme unit is converted to bilirubin, the pigment of bile, which is insoluble in plasma and attaches to plasma proteins for transport. Bilirubin is removed from the blood by the liver and conjugated with glucuronide to render it water soluble so that it can be excreted in the bile. Excess elimination of bilirubin in the bile due to increased red cell destruction can lead to the development of bilirubin gallstones. The plasma-insoluble form of bilirubin is referred to as unconjugated bilirubin and the water-soluble form as conjugated bilirubin. Serum levels of conjugated and unconjugated bilirubin can be measured in the laboratory and are reported as direct and indirect, respectively. If red cell destruction and consequent bilirubin production are excessive, unconjugated bilirubin accumulates in the blood. This results in a yellow discoloration of the skin, called jaundice.

When red blood cell destruction takes place in the circulation, as in hemolytic anemia, the hemoglobin remains in the plasma. The plasma contains a hemoglobin-binding protein called haptoglobin. Other plasma proteins, such as albumin, can also bind hemoglobin. With extensive intravascular destruction of red blood cells, hemoglobin levels may exceed the hemoglobin-binding capacity of haptoglobin and other plasma proteins. When this happens, free hemoglobin appears in the blood (i.e., hemoglobinemia) and is excreted in the urine (i.e., hemoglobinuria). Because excessive red blood cell destruction can occur in hemolytic transfusion reactions, urine samples are tested for free hemoglobin after a transfusion reaction.

**Red Cell Metabolism and Hemoglobin Oxidation**

The red blood cell, which lacks mitochondria, relies on glucose and the glycolytic pathway for its metabolic needs. The enzyme-mediated anaerobic metabolism of glucose generates the ATP needed for normal membrane function and ion transport. The depletion of glucose or the functional deficiency of one of the glycolytic enzymes leads to the premature death of the red blood cell. An offshoot of the glycolytic pathway is the production of 2,3-diphosphoglycerate (2,3-DPG), which binds to the hemoglobin molecule and reduces the affinity of hemoglobin for oxygen. This facilitates the release of oxygen at the tissue level. An increase in the concentration of 2,3-DPG occurs in conditions of chronic hypoxia such as chronic lung disease, anemia, and residence at high altitudes.

Certain chemicals (e.g., nitrates and sulfates) and drugs that oxidize hemoglobin to an inactive form interrupt the oxidation of hemoglobin (the combining of hemoglobin with oxygen). The nitrite ion reacts with hemoglobin to produce methemoglobin, which has a low affinity for oxygen. Large doses of nitrates can result in high levels of methemoglobin, causing pseudocyanosis and tissue hypoxia. For example, sodium nitrate, which is used in curing meats, can produce methemoglobin when taken in large amounts. In nursing infants, the intestinal flora is capable of converting significant amounts of inorganic nitrate (e.g., from well water) to nitrite.

A hereditary deficiency of glucose-6-phosphate dehydrogenase predisposes to oxidative denaturation of hemoglobin, with resultant red cell injury and lysis. Deficiency of G6PD is an anemia that is most frequently seen in black men. Hemolysis usually occurs as the result of oxidative stress generated by either an infection or exposure to certain drugs or foods.

**Laboratory Tests**

Red blood cells can be studied by means of a sample of blood (Table 27.1). In the laboratory, automated blood cell counters rapidly provide accurate measurements of red cell content and cell indices. The *red blood cell count* measures the total number of red blood cells in a microliter (µL) of blood. The *percentage of reticulocytes* (normally approximately 1%) provides an index of the rate of red cell production. The *hemoglobin* (grams per deciliter [dL] or 100 milliliters [mL] of blood)
measures the hemoglobin content of the blood. The major components of blood are the red cell mass and plasma volume. The hematocrit measures the red cell mass in a 100-mL plasma volume. To determine the hematocrit, a sample of blood is placed in a glass tube, which is then centrifuged to separate the cells and the plasma. The hematocrit may be deceptive because it varies with the quantity of extracellular fluid, rising with dehydration and falling with overexpansion of extracellular fluid volume (Fig. 27.6).

Red cell indices are used to differentiate types of anemias by size or color of red cells. The mean corpuscular volume (MCV) reflects the volume or size of the red cells. The MCV falls in microcytic (small cell) anemia and rises in macrocytic (large cell) anemia. Some anemias are normocytic (i.e., cells are of normal size or MCV). The mean corpuscular hemoglobin (MCH) is the concentration of hemoglobin in each cell. Hemoglobin accounts for the color of red blood cells. Anemias are described as normochromic (normal color or MCH) or hypochromic (decreased color or MCH). Mean cell hemoglobin (MCH) refers to the mass of the red cell and is less useful in classifying anemias.

A stained blood smear provides information about the size, color, and shape of red cells and the presence of immature or abnormal cells. If blood smear results are abnormal, examination of the bone marrow may be indicated. Bone marrow commonly is aspirated with a needle from the posterior iliac crest or the sternum. The aspirate is stained and observed for number and maturity of cells and abnormal types.

**IN SUMMARY**

The red blood cell provides the means for transporting oxygen from the lungs to the tissues. The biconcave shape of the red cell increases the surface area for diffusion of oxygen across the thin cell membrane. A complex cytoskeleton of proteins attached to the interior of the membrane maintains its shape and allows the cell to be deformed while passing through the small capillaries. The red cell contains hemoglobin, a molecule composed of two polypeptide chains each consisting of a globin (protein) portion and a heme unit, which surrounds an iron atom that combines reversibly with oxygen. Red cells develop from stem cells in the bone marrow and are released as reticulocytes into the blood, where they become mature erythrocytes. Red blood cell production is regulated by the hormone erythropoietin, which is produced by the kidney in response to a decrease in oxygen levels.

The life span of a red blood cell is approximately 120 days. Red cell destruction normally occurs in the
spleen, liver, bone marrow, and lymph nodes. In the process of destruction, the heme portion of the hemoglobin molecule is converted to bilirubin. Bilirubin, which is insoluble in plasma, attaches to plasma proteins for transport in the blood. It is removed from the blood by the liver and conjugated to a water-soluble form so that it can be excreted in the bile.¹

The red blood cell, which lacks mitochondria, relies on glucose and the glycolytic pathway for its metabolic needs. The end product of the glycolytic pathway, 2,3-DPG, increases the release of oxygen to the tissues during conditions of hypoxia by reducing hemoglobin’s affinity for oxygen.¹

In the laboratory, automated blood cell counters rapidly provide accurate measurements of red blood cell count and cell indices. A stained blood smear provides information about the size, color, and shape of red cells and the presence of immature or abnormal cells. If blood smear results are abnormal, examination of the bone marrow may be indicated.

**BLOOD TYPES AND TRANSFUSION THERAPY**

After completing this section of the chapter, you should be able to meet the following objectives:

- Differentiate red cell antigens from antibodies in people with type A, B, AB, or O blood.
- Explain the determination of the Rh factor.
- List the signs and symptoms of a blood transfusion reaction.

Anemias of various causes are treated with transfusions of whole blood or red blood cells only when oxygen delivery to the tissues is compromised, as evidenced by measures of oxygen transport and use, hemoglobin, and hematocrit. Current recommendations suggest transfusion for people with hemoglobin levels less than 7 g/dL, depending on age, illness, risk factors, and surgical procedures.¹,⁵

The red blood cell, which lacks mitochondria, relies on glucose and the glycolytic pathway for its metabolic needs. The end product of the glycolytic pathway, 2,3-DPG, increases the release of oxygen to the tissues during conditions of hypoxia by reducing hemoglobin’s affinity for oxygen.¹

In the laboratory, automated blood cell counters rapidly provide accurate measurements of red blood cell count and cell indices. A stained blood smear provides information about the size, color, and shape of red cells and the presence of immature or abnormal cells. If blood smear results are abnormal, examination of the bone marrow may be indicated.

**Chapter 27  Disorders of Red Blood Cells**

The donor cells with the recipient’s serum and observing for agglutination. If none appears, the donor and recipient blood types are compatible.

The use of autologous donation and transfusion has been advocated since the early 1980s. Autologous transfusion refers to the procedure of receiving one’s own blood—usually to replenish a surgical loss—thereby eliminating the risk of blood-borne disease or transfusion reaction.³ Autologous blood can be provided by several means—predeposit, hemodilution, and intraoperative salvage. A person who is anticipating elective orthopedic, vascular, or open heart surgery may predeposit blood (i.e., have the blood collected up to 6 weeks in advance and stored) for later transfusion during the surgery. Hemodilution involves phlebotomy before surgery with transfusion of the person’s blood at the completion of surgery. Intraoperative blood salvage is the collection of blood shed from the operative site for reinfusion into the person. Semiautomated devices are used to collect, anticoagulate, wash, and resuspend red cells for reinfusion during many procedures, including vascular, cardiac, and orthopedic surgery. As more and more surgeries are performed robotically, there will be less need to use autologous transfusions.

**ABO Blood Groups**

ABO compatibility is essential for effective transfusion therapy and requires knowledge of ABO antigens and antibodies. There are four major ABO blood groups determined by the presence or absence of two red cell antigens (A and B). People who have neither A nor B antigens are classified as having type O blood. Those with A antigens are classified as having type A blood; those with B antigens, as having type B blood; and those with A and B antigens, as having type AB blood (Table 27.3). The ABO blood groups are genetically determined. The type O gene is apparently functionless in production of a red cell antigen. Each of the other genes is expressed by the presence of a strong antigen on the surface of the red cell. Six genotypes, or gene combinations, result in four phenotypes, or blood type expressions. In the United States types O and A are the most common.

ABO antibodies predictably develop in the serum of people whose red cells lack the corresponding antigen. Persons with type A antigens on their red cells develop type B antibodies; persons with type B antigens develop type A antibodies in their serum; people with type O blood develop type A and type B antibodies; and people with type AB blood develop neither A nor B antibodies. The ABO antibodies usually are not present at birth but begin to develop at 3 to 6 months of age and reach maximum levels between the ages of 5 and 10 years.²

**Rh Types**

The D antigen of the Rh system is also important in transfusion compatibility and is routinely tested. The Rh type is coded by three gene pairs—C, c; D, d; and E, e. Each allele, with the exception of d, codes for a specific antigen. The D antigen is the most immunogenic. People who express the D antigen

*The composition of each type of blood component is described as well as the most common indications for using a given blood component. RBCs, platelets, and fresh frozen plasma are the blood products most commonly used. When transfusing these blood products, it is important to realize that the individual product is always “contaminated” with very small amounts of other blood products (e.g., WBCs mixed in a unit of platelets). This contamination can cause some difficulties, particularly isoantibodies, in certain patients.

are designated Rh positive, and those who do not express the D antigen are Rh negative. Unlike serum antibodies for the ABO blood types, which develop spontaneously after birth, Rh antibodies develop after exposure to one or more of the Rh antigens, usually through pregnancy or transfusions, and persist for many years. More than 80% of Rh-negative people develop the antibody to D antigen if they are exposed to Rh-positive blood. Because it takes several weeks to produce antibodies, a reaction may be delayed and usually is mild. If subsequent transfusions of Rh-positive blood are given to a person who has become sensitized, the person may have a severe, immediate reaction.
**Blood Transfusion Reactions**

The seriousness of blood transfusion reactions prompts the need for extreme caution when blood is administered. Because most transfusion reactions result from administrative errors or misidentification, care should be taken to identify correctly the recipient and the transfusion source. The recipient’s vital signs should be monitored before and during the transfusion, and careful observation for signs of transfusion reaction is imperative. The most lethal transfusion reaction is the destruction of donor red cells by reaction with antibody in the recipient’s serum. This immediate hemolytic reaction usually is caused by ABO incompatibility. The signs and symptoms of such a reaction include sensation of heat along the vein where the blood is being infused, flushing of the face, urticaria, headache, pain in the lumbar area, chills, fever, constriiction pain in the chest, cramping pain in the abdomen, nausea, vomiting, tachycardia, hypotension, and dyspnea. If any of these adverse effects occur, the transfusion should be stopped immediately. Access to a vein should be maintained because it may be necessary to infuse intravenous solutions to ensure diuresis, administer medications, and take blood samples. The blood must be saved for studies to determine the cause of the reaction.

Hemoglobin that is released from the hemolyzed donor cells is filtered in the glomeruli of the kidneys. Two possible complications of a blood transfusion reaction are oliguria and renal shutdown because of the adverse effects of the filtered hemoglobin on renal tubular flow. The urine should be examined for the presence of hemoglobin, urobilinogen, and red blood cells. Delayed hemolytic reactions may occur more than 10 days after transfusion and are caused by undetected antibodies in the recipient’s serum. The reaction is accompanied by a fall in hematocrit and jaundice, but most recipients are asymptomatic.

A febrile reaction is the most common transfusion reaction. Recipient antibodies directed against the donor’s white cells or platelets cause chills and fever. Platelet transfusions given for massive bleeding may have little to no effectiveness if the platelets are contaminated by leukocytes. Antipyretics are used to treat this reaction. Future febrile reactions may be avoided by the use of leukocyte-reduced blood.

Allergic reactions are caused by a person’s antibodies against donor proteins, particularly IgG. Urticaria and itching occur and can be relieved with antihistamines. Susceptible people may be transfused with washed red cells to prevent reactions.

**IN SUMMARY**

Transfusion therapy provides the means for replacement of red blood cells and other blood components. Red blood cells contain surface antigens, and reciprocal antibodies are found in the serum. Four major ABO blood types are determined by the presence or absence of two red cell antigens—A and B. The D antigen determines the Rh-positive type; absence of the D antigen determines the Rh-negative type. ABO and Rh types must be determined in recipient and donor blood before transfusion to ensure compatibility.

Anemia is defined as an abnormally low number of circulating red blood cells or level of hemoglobin, or both, resulting in diminished oxygen-carrying capacity. Anemia usually results from excessive loss (bleeding) or destruction (hemolysis) of red blood cells or from deficient red blood cell production because of a lack of nutritional elements or bone marrow failure.

Anemia is not a disease, but an indication of some disease process or alteration in body function. The effects of anemia can be grouped into three categories:

1. Manifestations of impaired oxygen transport and the resulting compensatory mechanisms
2. Reduction in red cell indices and hemoglobin levels
3. Signs and symptoms associated with the pathologic process that is causing the anemia

The manifestations of anemia depend on its severity, the rapidity of its development, and the person’s age and health status. In anemia, the oxygen-carrying capacity of hemoglobin is reduced, causing tissue hypoxia. Tissue hypoxia can give rise to fatigue, weakness, dyspnea, and sometimes angina. Hypoxia of brain tissue results in headache, faintness, and dim vision. The redistribution of the blood from cutaneous tissues or a lack of hemoglobin causes pallor of the skin, mucous membranes, conjunctiva, and nail beds. Tachycardia and palpitations may occur as the body tries to compensate with an increase in cardiac output. A flow-type systolic heart murmur may result from changes in blood viscosity. Ventricular hypertrophy and high-output heart failure may develop in people with severe anemia, particularly those with preexisting heart disease. Erythropoiesis is accelerated and may be recognized by diffuse bone pain and sternal tenderness. In addition to the common anemic manifestations, hemolytic anemias are...
Loss, circulatory shock and circulatory collapse may occur.

The bleeding loss is internal or external. With rapid blood loss anemia depend on the rate of hemorrhage and whether the cause is intrinsic or extrinsic. Intrinsic anemia and jaundice.

Laboratory tests are useful in determining the severity and cause of the anemia. The red cell count and hemoglobin levels provide information about the severity of the anemia, whereas red cell characteristics such as size (normocytic, microcytic, macrocytic), color (normochromic, hypochromic), and shape often provide information about the cause of anemia (Fig. 27.7).1

Laboratory tests are useful in determining the severity and cause of the anemia. The red cell count and hemoglobin levels provide information about the severity of the anemia, whereas red cell characteristics such as size (normocytic, microcytic, macrocytic), color (normochromic, hypochromic), and shape often provide information about the cause of anemia (Fig. 27.7).1

**Hemolytic Anemias**

Hemolytic anemia is characterized by

- The premature destruction of red cells
- The retention in the body of iron and the other products of hemoglobin destruction
- An increase in erythropoiesis

Almost all types of hemolytic anemia are distinguished by normocytic and normochromic red cells. Because of the red blood cell’s shortened life span, the bone marrow usually is hyperactive, resulting in an increased number of reticulocytes in the circulating blood. As with other types of anemias, the person experiences easy fatigability, dyspnea, and other signs and symptoms of impaired oxygen transport.

In hemolytic anemia, red cell breakdown can occur within or outside the vascular compartment. Intravascular hemolysis is less common and occurs as a result of complement fixation in transfusion reactions, mechanical injury, or toxic factors. It is characterized by hemoglobinemia, hemoglobinuria, jaundice, and hemosiderinuria. Extravascular hemolysis occurs when red cells become less deformable, making it difficult for them to traverse the splenic sinusoids. The abnormal red cells are sequestered and phagocytized by macrophages in the spleen. The manifestations of extravascular hemolysis include anemia and jaundice.

Another classification of hemolytic anemia is based on whether the cause is intrinsic or extrinsic. Intrinsic causes include defects of the red cell membrane, the various...
hemoglobinopathies, and inherited enzyme defects. Two main types of hemoglobinopathies can cause red cell hemolysis: the abnormal substitution of an amino acid in the hemoglobin molecule, as in sickle cell disease, and the defective synthesis of one of the polypeptide chains that form the globin portion of hemoglobin, as in the thalassemias.

Extrinsic or acquired forms of hemolytic anemia are caused by agents external to the red blood cell, such as drugs, bacterial and other toxins, antibodies, and physical trauma. Although all these factors can cause premature and accelerated destruction of red cells, they cannot all be treated in the same way. Some respond to splenectomy, others to treatment with corticosteroid hormones, and still others do not resolve until the primary disorder is corrected.

Inherited Hemolytic Anemias
There are also a group of inherited hemolytic anemias such as sickle cell anemia, thalassemia, and hereditary spherocytosis. People who inherit one of these anemias can have very different clinical manifestations, depending on the genotype they have. In fact, a person could be acutely ill or may have little to no clinical manifestations.

Hereditary Spherocytosis. Hereditary spherocytosis is mostly transmitted as an autosomal dominant trait and is the most common inherited disorder of the red cell membrane. The disorder is caused by abnormalities of the spectrin, ankyrin, protein 4.2, or band 3 membrane proteins that lead to a gradual loss of the membrane surface. The loss of membrane relative to cytoplasm causes the cell to lose its lipid bilayer from the RBC cytoskeleton. The RBC forms a spherical shape and cannot easily traverse the spleen. Gradually most of these RBCs lose more of their surface membrane and die.

Clinical signs are variable but typically include mild hemolytic anemia, jaundice, splenomegaly, and bilirubin gallstones. A life-threatening aplastic crisis may occur when a sudden disruption of red cell production (often from a parvovirus B19) causes a rapid drop in hematocrit and the hemoglobin level. The disorder usually is treated with splenectomy to reduce red cell destruction. Blood transfusions may be required in a crisis.

Sickle Cell Disease. Sickle cell disease is an inherited disorder in which an abnormal hemoglobin (hemoglobin S [HbS]) leads to chronic hemolytic anemia, pain, and organ failure. The HbS gene is transmitted by recessive inheritance and can manifest as sickle cell trait (i.e., heterozygote with one HbS gene) or sickle cell disease (i.e., homozygote with two HbS genes). Sickle cell disease affects approximately 70,000 to 100,000 Americans. In parts of Africa, where malaria is endemic, people with sickle cell anemia have a slight protective effect against Plasmodium falciparum malaria.

Etiology and Pathogenesis. The abnormal structure of HbS results from a point mutation in the \( \beta \) chain of the hemoglobin molecule, with an abnormal substitution of a single amino acid, valine, for glutamic acid (Fig. 27.8). Variations in proportions exist, and the concentration of HbS correlates with the risk of sickling. In the homozygote with sickle cell disease, the HbS becomes sickled when deoxygenated or at a low oxygen tension. The deoxygenated hemoglobin aggregates and polymerizes in the cytoplasm, creating a semisolid gel that changes the shape and deformability of the cell. The sickled cell may return to normal shape with oxygenation in the lungs. However, after repeated episodes of deoxygenation, the cells remain permanently sickled. The person with sickle cell trait who has less HbS has little tendency to sickle and is virtually asymptomatic. HbF inhibits the polymerization of HbS. Therefore, most infants with sickle cell disease do not begin to experience the effects of the sickling until after 8 to 10 weeks of age, when the HbF has been replaced by HbS.

There are two major consequences of red blood cell sickling—chronic hemolytic anemia and blood vessel occlusion. Premature destruction of the cells due to the rigid, nondeformable membrane occurs in the spleen, causing hemolysis and anemia from a decrease in red cell numbers. Vessel occlusion is a complex process involving an interaction among the sickled cells, endothelial cells, leukocytes, platelets, and other plasma proteins. Factors associated with sickling and vessel
occlusion include cold, stress, physical exertion, infection, and illnesses that cause hypoxia, dehydration, or acidosis. The rate of HbS polymerization is affected by the concentration of hemoglobin in the cell. Dehydration increases the hemoglobin concentration and contributes to the polymerization and resulting sickling. Acidosis reduces the affinity of hemoglobin for oxygen, resulting in more deoxygenated hemoglobin and increased sickling.

**Clinical Manifestations.** People who are homozygous for the HbS gene experience severe hemolytic anemia, chronic hyperbilirubinemia, and vasoocclusive crises. The hyperbilirubinemia that results from the breakdown products of hemoglobin often leads to jaundice and the production of pigment stones in the gallbladder.

Blood vessel occlusion causes most of the severe complications. An acute pain episode results from vessel occlusion and hypoxia and can occur suddenly in almost any part of the body. Commonly, obstruction by sickled cells occurs in the abdomen, chest, bones, and joints. Many areas may be affected simultaneously. Infarctions caused by sluggish blood flow may cause chronic damage to the liver, spleen, heart, kidneys, retina, and other organs (Fig. 27.9). Acute chest syndrome is an atypical pneumonia resulting from pulmonary infarction. It is a leading cause of hospitalization in people with sickle cell disease and is characterized by pulmonary infiltrates, which cause dyspnea, cough, and chest discomfort. The syndrome can cause chronic respiratory insufficiency and is a leading cause of death in sickle cell disease. Children may experience growth retardation and susceptibility to osteomyelitis. Painful bone crises may be caused by marrow infarcts of the bones of the hands and feet, resulting in swelling of those extremities. Transient ischemic attack or cerebral hemorrhage may precede a stroke.

The spleen is especially susceptible to damage by HbS. Because of the spleen’s sluggish blood flow and low oxygen tension, hemoglobin in red cells traversing the spleen becomes deoxygenated, causing ischemia. Splenic injury begins in early childhood, characterized by intense congestion, and is usually asymptomatic. The congestion causes functional asplenia and predisposes the person to life-threatening infections by encapsulated organisms, including Streptococcus pneumoniae, Haemophilus influenzae type b, and Klebsiella species. Neonates and small children have not had time to create antibodies to these organisms and rely on the spleen for their removal. In the absence of specific antibody to the polysaccharide capsular antigens of these organisms, splenic activity is essential for removing these organisms when they enter the blood.

**Diagnosis and Screening.** Neonatal diagnosis of sickle cell disease is made on the basis of clinical findings and hemoglobin solubility results, which are confirmed by hemoglobin electrophoresis.

In the United States, screening programs have been implemented to detect newborns with sickle cell disease and other hemoglobinopathies. Cord blood or heel-stick samples are subjected to electrophoresis to separate the HbF from the small amount of HbA and HbS. Other hemoglobins may be detected and quantified by further laboratory evaluation. Many states mandate screening of all newborns, regardless of ethnic origin.

**Treatment.** Currently, there is no known cure for sickle cell disease. Therefore, treatment strategies focus on prevention of sickling episodes, symptom management, and treatment of complications. The person is advised to avoid situations that precipitate sickling episodes, such as infections, cold exposure, severe physical exertion, acidosis, and dehydration. Infections are aggressively treated, and blood transfusions may be warranted in a crisis or given chronically in severe disease.
Most children with sickle cell disease are at risk for sepsis from encapsulated organisms during the first 3 years of life. Maintaining full immunization, including *H. influenzae* vaccine and Hepatitis B vaccine, is recommended. Hydroxyurea is a cytotoxic drug used to prevent complications of sickle cell disease and is recommended as a standard of care for all with sickle cell disease.\textsuperscript{12} The drug allows synthesis of more HbF and less HbS, thereby decreasing sickling. However, long-term effects regarding organ damage, growth and development, and risk of malignancies are unknown. Bone marrow or stem cell transplantation has the potential for cure in symptomatic children but carries multiple risks for complications. Currently many people with sickle cell disease are treated with anticoagulation therapy, such as heparin and warfarin, to prevent more thrombotic and vasoocclusive disorders. However, there are no data to support that this is effective with sickle cell disease.\textsuperscript{13}

**The Thalassemias.** The thalassemias are a group of inherited disorders of hemoglobin synthesis leading to decreased synthesis of either the α- or β-globin chains of HbA. β-Thalassemias are caused by deficient synthesis of the β chain and α-thalassemias by deficient synthesis of the α chain.\textsuperscript{1} The defect is inherited as a mendelian trait, and a person may be heterozygous for the trait and have a mild form of the disease or be homozygous and have the severe form of the disease. Like sickle cell disease, the thalassemias occur with high degree of frequency in certain populations. The β-thalassemias, sometimes called *Cooley anemia* or *Mediterranean anemia*, are most common in the Mediterranean populations of southern Italy and Greece, and the α-thalassemias are most common among Asians. Both β- and α-thalassemias are common in Africans and Americans of African descent.

Two factors contribute to the anemia that occurs in thalassemia: low intracellular hemoglobin (hypochromia) due to the decreased synthesis of the affected chain coupled with continued production and accumulation of the unaffected globin chain. The reduced hemoglobin synthesis results in a hypochromic, microcytic anemia, whereas the accumulation of the unaffected chain interferes with normal red cell maturation and contributes to membrane changes that lead to hemolysis and anemia.

**The β-Thalassemias.** The β-thalassemias result from multiple point mutations in the β-globin gene causing a defect in β-chain synthesis. In β-thalassemias, the excess α chains are denatured to form precipitates (*i.e.*, Heinz bodies) in the bone marrow red cell precursors. The Heinz bodies impair DNA synthesis and cause damage to the red cell membrane. Severely affected red cell precursors are destroyed in the bone marrow. Those that escape intramedullary death are at increased risk of destruction in the spleen. In addition to the anemia, people with moderate to severe forms of the disease suffer from coagulation abnormalities.

The clinical manifestations of the β-thalassemias are based on the severity of the anemia. The presence of one normal gene in heterozygous persons (thalassemia minor) usually results in sufficient normal hemoglobin synthesis to prevent severe anemia. People who are homozygous for the trait (thalassemia major) have severe, blood transfusion–dependent anemia that is evident at 6 to 9 months of age when the hemoglobin switches from HbF to HbA. If transfusion therapy is not started early in life, severe growth retardation occurs in children with the disorder.

In severe β-thalassemia, marked anemia produced by ineffective hematopoiesis and hemolysis leads to increased erythropoietin secretion and hyperplasia in the bone marrow and sites of extramedullary hematopoiesis. The expanding mass of erythropoietic marrow invades the bony cortex, impairs bone growth, and produces other bone abnormalities. There is thinning of the cortical bone, with new bone formation evident on the maxilla and frontal bones of the face (*i.e.*, chipmunk facies). The long bones, ribs, and vertebrae may become vulnerable to fracture because of osteoporosis or osteopenia, which contributes to increased morbidity in older people. Enlargement of the spleen (splenomegaly) and liver (hepatomegaly) results from extramedullary hematopoiesis and increased red cell destruction.

Iron overload is a major complication of β-thalassemia. Excess iron stores, which accumulate from increased dietary absorption and repeated transfusions, are deposited in the myocardium, liver, and endocrine organs and induce organ damage. Cardiac, hepatic, and endocrine diseases are common causes of morbidity and mortality from iron overload.

Regular blood transfusions to maintain hemoglobin levels at 9 to 10 g/dL improve growth and development and prevent most of the complications, and iron chelation therapy can reduce the iron overload and extend life expectancy.\textsuperscript{14} Stem cell transplantation is a potential cure for low-risk people, particularly in younger people with no complications of the disease or its treatment, and has excellent results.\textsuperscript{15} In the future, stem cell gene replacement may provide a cure for many with the disease.

**The α-Thalassemias.** The α-thalassemias are caused by a gene deletion that results in defective α-chain synthesis.\textsuperscript{14} Synthesis of the α-globin chains of hemoglobin is controlled by two pairs or four genes. Hence, α-thalassemia shows great variation in severity related to the number of gene deletions. Silent carriers who have a deletion of a single α-globin gene are asymptomatic, and those with deletion of two genes have the α-thalassemia trait and exhibit mild hemolytic anemia. Deletion of three of the four α-chain genes leads to unstable aggregates of α chains called *hemoglobin H* (HbH). This disorder is the most important clinical form and is common in Asians. The β chains are more soluble than the α chains, and their accumulation is less toxic to the red cells, so that senescent rather than precursor red cells are affected. Most people with HbH have chronic moderate hemolytic anemia and may require blood transfusions in time of fever or illness or with certain medications.\textsuperscript{14} The most severe form of α-thalassemia occurs in infants in whom all four α-globin
genes are deleted and is called hydrops fetalis syndrome. Such a defect results in a hemoglobin molecule (Hb Bart) that is formed exclusively from the chains of HbF. Hb Bart, which has an extremely high oxygen affinity, cannot release oxygen in the tissues.\textsuperscript{14} Hydrops fetalis syndrome usually results in death in utero or shortly after birth.

**Inherited Enzyme Defects.** The most common inherited enzyme defect that results in hemolytic anemia is a deficiency of glucose-6-phosphate dehydrogenase (G6PD).\textsuperscript{15} The gene that determines this enzyme is located on the X chromosome, and the defect is expressed only in males and homozygous females. There are multiple genetic variants of this disorder found in all populations but particularly in African and Mediterranean groups.\textsuperscript{15} The disorder makes red cells more vulnerable to oxidants and causes direct oxidation of hemoglobin to methemoglobin, which cannot transport oxygen, and denaturing of the hemoglobin molecule to form Heinz bodies, which are precipitated in the red blood cell. Hemolysis usually occurs as the damaged red blood cells move through the narrow vessels of the spleen, causing hemoglobinemia, hemoglobinuria, and jaundice. The hemolysis is short-lived, occurring 2 to 3 days after the trigger event. In black people, the defect is mildly expressed and is not associated with chronic hemolytic anemia unless triggered by oxidant drugs, acidosis, or infection.

The antimalarial drug primaquine, the sulfonamides, nitrofurantoin, aspirin, phenacetin, some chemotherapeutics, and other drugs cause hemolysis.\textsuperscript{15} Free radicals generated by phagocytes during infections also are possible triggers. The disorder can be diagnosed through the use of a G6PD assay or screening test.

**Acquired Hemolytic Anemias**

Several acquired factors exogenous to the red blood cell produce hemolysis by direct membrane destruction or by antibody-mediated lysis.\textsuperscript{1} Various drugs, chemicals, toxins, venoms, and infections such as malaria destroy red cell membranes. Hemolysis can also be caused by mechanical factors such as prosthetic heart valves, vasculitis, and severe burns. Obstructions in the microcirculation, as in disseminated intravascular coagulation, thrombotic thrombocytopenic purpura, and renal disease, may traumatize the red cells by producing turbulence and changing pressure gradients.

Many hemolytic anemias are immune mediated, caused by antibodies that destroy the red cell. Autoantibodies may be produced in response to drugs and disease. Alloantibodies come from an exogenous source and are responsible for transfusion reactions and hemolytic disease of the newborn.\textsuperscript{1,16}

The autoantibodies that cause red cell destruction are of two types: warm-reacting antibodies of the immunoglobulin G (IgG) type, which are maximally active at 37°C, and cold-reacting antibodies of the IgM type, which are optimally active at or near 4°C.\textsuperscript{1,16}

The warm-reacting antibodies cause no morphologic or metabolic alteration in the red cell. Instead, they react with antigens on the red cell membrane, causing destructive changes that lead to spherocytosis, with subsequent phagocytic destruction in the spleen or reticuloendothelial system (RES). They lack specificity for the ABO antigens but may react with the Rh antigens. The reactions have a rapid onset and may be severe and life-threatening. Fatigue is a common complaint and jaundice and moderate splenomegaly are present. Angina or congestive heart failure may also occur. There are varied causes for this anemia. Approximately 50% are idiopathic, and 50% are drug induced (e.g., penicillin) or related to some other disorder. The drug-induced hemolysis is commonly benign.

The cold-reacting antibodies activate complement. Chronic hemolytic anemia caused by cold-reacting antibodies occurs with lymphoproliferative disorders and as an idiopathic disorder of unknown cause.\textsuperscript{1} The hemolytic process occurs in distal body parts, where the temperature may fall below 30°C. Vascular obstruction by red cells results in pallor, cyanosis of the body parts exposed to cold temperatures, and Raynaud phenomenon. Hemolytic anemia caused by cold-reacting antibodies develops in only a few people and is rarely severe.

The Coombs test, or antiglobulin test, is used to diagnose immune hemolytic anemias. It detects the presence of antibody or complement on the surface of the red cell. The direct antiglobulin test (DAT) detects the antibody on red blood cells. In this test, red cells that have been washed free of serum are mixed with anti-human globulin reagent.\textsuperscript{17} The red cells agglutinate if the reagent binds to and bridges the antibody or complement on adjacent red cells. The DAT result is positive in cases of autoimmune hemolytic anemia, erythroblastosis fetalis (Rh disease of the newborn), transfusion reactions, and drug-induced hemolysis. The indirect antiglobulin test detects antibody in the serum, and the result is positive for specific antibodies. It is used for antibody detection and cross-matching before transfusion.

**Anemias of Deficient Red Cell Production**

Anemia may result from the decreased production of erythrocytes by the bone marrow. A deficiency of nutrients for hemoglobin synthesis (iron) or DNA synthesis (cobalamin or folic acid) may reduce red cell production by the bone marrow. A deficiency of red cells also results when the marrow itself fails or is replaced by nonfunctional tissue.

**Iron Deficiency Anemia**

Iron deficiency is a common worldwide cause of anemia affecting people of all ages. The anemia results from dietary deficiency, loss of iron through bleeding, or increased demands. Because iron is a component of heme, a deficiency leads to decreased hemoglobin synthesis and consequent impairment of oxygen delivery.

**Etiology and Pathogenesis.** Body iron is used for multiple mechanisms every day. When red cells become senescent
and are broken down, their iron is released and reused in the production of new red cells. Despite this efficiency, small amounts of iron are lost in the feces and need to be replaced by dietary uptake. Iron balance is maintained by the absorption of 1 to 2 mg daily to replace the iron lost in the feces.1 The average western diet supplies about 20 mg.1 The absorbed iron is more than sufficient to supply the needs of most people but may be barely adequate in toddlers, adolescents, and women of childbearing age. Dietary deficiency of iron is not common in developed countries except in certain populations. Most iron is derived from meat, and when meat is not available, as for deprived populations, or is not a dietary constituent, as for vegetarians, iron deficiency may occur.

The usual reason for iron deficiency in adults in the western world is chronic blood loss because iron cannot be recycled to the pool. In men and postmenopausal women, blood loss may occur from gastrointestinal bleeding because of peptic ulcer, vascular lesions, intestinal polyps, hemorrhoids, or cancer. Although cessation of menstruation removes a major source of iron loss in the pregnant woman, iron requirements increase at this time, and deficiency is common.18 Evidence demonstrates that pregnant women with iron deficiency anemia on iron supplementation did not experience more fetal loss or fetal congenital problems compared to women who had adequate iron levels and were not on supplementation.18 However, pregnant women with iron deficiency anemia without iron supplementation had a slightly higher rate of preterm infants and lower birth rates than those supplemented with iron.18

A child’s growth places extra demands on the body. Blood volume increases, with a greater need for iron. Iron requirements are proportionally higher in infancy (3 to 24 months) than at any other age, although they are also increased in childhood and adolescence. In infancy, the two main causes of iron deficiency anemia are low iron levels at birth because of maternal deficiency and a diet consisting mainly of cow’s milk, which is low in absorbable iron.

Remember Mrs. Cretena from the unit opener case study who was diagnosed with a microcytic hypochromic anemia that turned out to be iron deficiency anemia? Her PCP referred her to a nutritionist last week. At this visit, she explained that she was a vegetarian and did not eat any red meat. Her dietary history also revealed that she did not have sufficient amounts of protein and iron in her daily diet. Mrs. Cretena came in today for a follow-up visit with her PCP. She volunteered more information regarding her heavy menses at this second visit. She said that she was saturating approximately 16 large pads/day, which was up from her “normal” amount of about 10 large pads/day. When asked when she last visited her gynecologist, she replied that it had been about 10 years ago (after her last child was born). A gynecologist visit was made for her immediately following this primary care visit.

Clinical Manifestations. The manifestations of iron deficiency anemia are related to impaired oxygen transport and lack of hemoglobin. Depending on the severity of the anemia, fatigability, palpitations, dyspnea, angina, and tachycardia may occur. Epithelial atrophy is common and results in waxy pallor, brittle hair and nails, sometimes a spoon-shaped deformity of the fingernails called koilonychia, smooth tongue, sores in the corners of the mouth, and sometimes dysphagia and decreased acid secretion.

Diagnosis and Treatment. Low hemoglobin and hematocrit, decreased iron stores, and low serum iron and ferritin characterize iron deficiency anemia. The red cells are decreased in number and are microcytic and hypochromic (see Fig. 27.7). Poikilocytosis (irregular shape) and anisocytosis (irregular size) are also present. Laboratory values indicate reduced MCHC and MCV. Membrane changes may predispose to hemolysis, causing further loss of red cells.

Prevention of iron deficiency is a primary concern in infants and children. Avoidance of cow’s milk, iron supplementation at 4 to 6 months of age in breast-fed infants, and use of iron-fortified formulas and cereals are recommended for infants younger than 1 year of age.19 In the 2nd year, a diet rich in iron-containing foods and use of iron-fortified vitamins will help prevent iron deficiency. The treatment of iron deficiency anemia in children and adults is directed toward controlling chronic blood loss, increasing dietary intake of iron, and administering supplemental iron. Ferrous sulfate, which is the usual oral replacement therapy, replenishes iron stores in several months.

Megaloblastic Anemias

Megaloblastic anemias are caused by impaired DNA synthesis that results in enlarged red cells (MCV > 100 fL) due to impaired maturation and division.1 Vitamin B₁₂, and folic acid deficiencies are the most common conditions associated with megaloblastic anemias. Because megaloblastic anemias develop slowly, there are often few symptoms until the anemia is far advanced.1

Vitamin B₁₂-Deficiency Anemia. Vitamin B₁₂, also known as cobalamin, serves as a cofactor for two important reactions in humans. It is essential for DNA synthesis and nuclear maturation, which in turn leads to normal red cell maturation...
and division. Vitamin $B_12$ is also involved in a reaction that prevents abnormal fatty acids from being incorporated into neuronal lipids. This abnormality may predispose to myelin defects in this pathway may cause a deficiency.

**Etiology and Pathogenesis.** Vitamin $B_{12}$ is found in all foods of animal origin. Dietary deficiency is rare and usually found only in strict vegetarians who avoid all dairy products as well as meat and fish. Normal body stores of 1000 to 5000 micrograms ($\mu g$) provide the daily requirement of 1 $\mu g$ for a number of years. Therefore, deficiency of vitamin $B_{12}$ develops slowly. Vitamin $B_{12}$ is absorbed by a unique process. After release from the animal protein, it is bound to intrinsic factor, a protein secreted by the gastric parietal cells (Fig. 27.10). The vitamin $B_{12}$–intrinsic factor complex protects vitamin $B_{12}$ from digestion by intestinal enzymes. The complex travels to the ileum, where it binds to membrane receptors on the epithelial cells. Vitamin $B_{12}$ is then separated from intrinsic factor and transported across the membrane into the circulation. There it is bound to its carrier protein, transcobalamin II, which transports vitamin $B_{12}$ to its storage and tissue sites. Any defects in this pathway may cause a deficiency.

**Pernicious anemia** is a specific form of megaloblastic anemia caused by atrophic gastritis and failure to produce intrinsic factor that leads to failure to absorb vitamin $B_{12}$. Pernicious anemia is believed to result from immunologically mediated, possibly autoimmune, destruction of the gastric mucosa. The resultant chronic atrophic gastritis is marked by loss of parietal cells and production of antibodies that interfere with binding of vitamin $B_{12}$ to intrinsic factor. Other causes of vitamin $B_{12}$–deficiency anemia include gastrectomy, ileal resection, inflammation or neoplasms in the terminal ileum, and malabsorption syndromes. The hallmark of vitamin $B_{12}$ deficiency is megaloblastic anemia. When vitamin $B_{12}$ is deficient, the red cells that are produced are abnormally large because of excess cytoplasmic growth and structural proteins (see Fig. 27.7). The cells have immature nuclei and show evidence of cellular destruction. They have flimsy membranes and are oval rather than biconcave. These oddly shaped cells have a short life span that can be measured in weeks rather than months.

**Clinical Manifestations.** The loss of red cells results in a moderate to severe anemia and mild jaundice. The MCV is elevated since the cells are larger than normal, and the MCHC is normal. Neurologic changes that accompany the disorder are caused by deranged methylation of myelin protein. Demyelination of the dorsal and lateral columns of the spinal cord causes symmetric paresthesias of the feet and fingers, loss of vibratory and position sense, and eventual spastic ataxia. In more advanced cases, cerebral function may be altered. In some cases, confusion and dementia and other neuropsychiatric changes may precede hematologic changes.

**Diagnosis and Treatment.** Diagnosis of vitamin $B_{12}$ deficiency is made by finding an abnormally low vitamin $B_{12}$ serum level. The Schilling test, which measures the 24-hour urinary excretion of radiolabeled vitamin $B_{12}$ administered orally, has been used in the past to document decreased absorption of vitamin $B_{12}$. Currently, the diagnosis of pernicious anemia is usually made by the detection of parietal cell and intrinsic factor antibodies. Lifelong treatment consisting of intramuscular injections or high oral doses of vitamin $B_{12}$ reverses the anemia and improves the neurologic changes.

**Folic Acid Deficiency Anemia.** Folic acid is also required for DNA synthesis and red cell maturation, and its deficiency produces the same type of megaloblastic red cell changes that occur in vitamin $B_{12}$–deficiency anemia (i.e., increased MCV and normal MCHC). Symptoms are also similar, but without the neurologic manifestations.

Folic acid is readily absorbed from the intestine. It is found in vegetables (particularly the green leafy types), fruits, cereals, and meats. Much of the vitamin, however, is lost in cooking. The most common causes of folic acid deficiency are malnutrition or dietary lack of folic acid, especially in older adults or in association with alcoholism. Total body stores of folic acid amount to 2000 to 5000 $\mu g$, and 50 $\mu g$ is required in the daily diet. A dietary deficiency may result in anemia in a few months. Malabsorption of folic acid may be due to syndromes such as celiac disease or other intestinal disorders. Some drugs used to treat seizure disorders (e.g., primidone, phenytoin, phenobarbital) and triamterene, a diuretic, interfere with folic acid absorption. In neoplastic disease, tumor cells
compete for folate, and deficiency is common. Methotrexate, a folic acid analog used in the treatment of cancer, can also impair the action of folic acid by blocking its conversion to the active form.

Because pregnancy increases the need for folic acid 5- to 10-fold, a deficiency commonly occurs. Poor dietary habits, anorexia, and nausea are other reasons for folic acid deficiency during pregnancy. It is well known there is an association between folate deficiency and neural tube defects in the growing fetus, so all childbearing women who are sexually active are advised to evaluate their folate intake so it is high enough to prevent neural tube defects in their offspring.

**Aplastic Anemia**

Aplastic anemia describes a disorder of pluripotential bone marrow stem cells that results in a reduction of all three hematopoietic cell lines—red blood cells, white blood cells, and platelets. Pure red cell aplasia, in which only the red cells are affected, rarely occurs. Anemia results from the failure of the marrow to replace senescent red cells that are destroyed and leave the circulation, although the cells that remain are of normal size and color. At the same time, because the leukocytes, particularly the neutrophils, and the thrombocytes have a short life span, a deficiency of these cells usually is apparent before the anemia becomes severe.

**Etiology and Pathogenesis.** Among the causes of aplastic anemia are exposure to high doses of radiation, chemicals, and toxins that suppress hematopoiesis directly or through immune mechanisms. Chemotherapy and irradiation commonly result in bone marrow depression, which causes pancytopenia (anemia, thrombocytopenia, and neutropenia). Identified toxic agents include benzene, the antibiotic chloramphenicol, and the alkylating agents and antimetabolites used in the treatment of cancer. Aplastic anemia caused by exposure to chemical agents may be an idiosyncratic reaction because it affects only certain susceptible people. It typically occurs weeks after a drug is initiated but can occur earlier. Such reactions often are severe and sometimes irreversible and fatal. Aplastic anemia can develop in the course of many infections and has been reported most often as a complication of viral hepatitis, mononucleosis, and other viral illnesses, including acquired immunodeficiency syndrome (AIDS). In two thirds of cases, the cause is unknown, and these are called **idiopathic aplastic anemia.** The mechanisms underlying the pathogenesis of aplastic anemia are unknown. It is suggested that exposure to the chemicals, infectious agents, and other insults generates a cellular immune response resulting in production of cytokines by activated T cells. These cytokines (e.g., interferon, tumor necrosis factor [TNF]) then suppress normal stem cell growth and development.

**Clinical Manifestations.** The onset of aplastic anemia may be insidious, or it may strike with suddenness and great severity. It can occur at any age. The initial presenting symptoms include weakness, fatigability, and pallor caused by anemia. Petechiae (i.e., small, punctate skin hemorrhages) and ecchymoses (i.e., bruises) often occur on the skin, and bleeding from the nose, gums, vagina, or gastrointestinal tract may occur because of decreased platelet levels. The decrease in the number of neutrophils increases susceptibility to infection.

**Diagnosis and Treatment.** With aplastic anemia there is a gradual onset with some fatigue or possibly some bleeding from the gums or the person may complain that he is having difficulty clotting. Once the person presents to the physician, the aplastic anemia may be life threatening. There are no specific physical findings such as hepatosplenomegaly or lymphadenopathy. The complete blood count (CBC) shows pancytopenia, which means decreased red and white blood cells and platelets. Reticulocyte count is zero since the marrow is not producing any blood cells. The RBC indices indicate normochromic and normocytic anemia.

Perhaps one of the most helpful findings to determine the etiology of the pancytopenia is determined in the patient’s history. Most likely the patient has taken a drug or acquired a virus, which has caused the aplastic anemia.

Therapy for aplastic anemia in the young and severely affected includes stem cell replacement by bone marrow, peripheral blood transplantation, or immunosuppressive therapy. Histocompatible donors supply the stem cells to replace the person’s destroyed marrow cells. Graft-versus-host disease, rejection, and infection are major risks of the procedure. For those who are not transplantation candidates, immunosuppressive therapy with lymphocyte immune globulin prevents suppression of proliferating stem cells, producing remission but generally not as long lasting as bone marrow transplantation. People with aplastic anemia should avoid the offending agents and be treated with antibiotics for infection.

**Chronic Disease Anemias**

Anemia often occurs as a complication of chronic infections, inflammation, and cancer. Common causes of chronic kidney disease (CKD) anemias are acute and chronic infections, including AIDS and osteomyelitis; cancers; autoimmune disorders such as rheumatoid arthritis, systemic lupus erythematosus, and inflammatory bowel disease; and CKD. Additionally, anemia of CKD can cause left ventricular hypertrophy. Evidence suggests hepcidin may become a target for treating anemia of CKD in the future. It is theorized that the short red cell life span, deficient red cell production, a decreased response to erythropoietin, and low serum iron are caused by actions of cytokines and cells of the RES. Microorganisms, tumor cells, and autoimmune dysregulation lead to T-cell activation and production of cytokines (e.g., interleukin-1, interferon, and TNF) that suppress the erythropoietin response. In addition, macrophages take up iron and store it, thus reducing its availability for erythropoiesis. The mild anemia is normocytic and normochromic with low reticulocyte counts.
Chronic renal failure almost always results in anemia, primarily because of a deficiency of erythropoietin. Unidentified uremic toxins and retained nitrogen also interfere with the actions of erythropoietin and with red cell production and survival. Hemolysis and blood loss associated with hemodialysis and bleeding tendencies also contribute to the anemia of renal failure. Therapy for these anemias includes treatment for the underlying disease, short-term erythropoietin therapy, iron supplementation, and blood transfusions. However, it is questionable if erythropoietin may also cause adverse effects such as cardiovascular disease. “Anemia of critical illness” is common in the intensive care unit, with more than 90% of people having low hemoglobin levels secondary to their comorbidities. In critically ill people, low erythropoietin concentrations and anemia also appear to be caused by inflammatory cytokines. In this population, it is suggested that red blood cell transfusions be restricted to reduce the risk of transmission of infectious agents and immune modulation.

**IN SUMMARY**

Anemia is a condition of an abnormally low number of circulating red blood cells or hemoglobin level, or both. It is not a disease, but a manifestation of a disease process or alteration in body function. The manifestations of anemia are those associated with impaired oxygen transport; alterations in red blood cell number, hemoglobin content, and cell structure; and the signs and symptoms of the underlying process causing the anemia.

Anemia can result from excessive blood loss, red cell destruction due to hemolysis, or deficient hemoglobin or red cell production. Blood loss anemia can be acute or chronic. With bleeding, iron and other components of the erythrocyte are lost from the body. Hemolytic anemia is characterized by the premature destruction of red cells, with retention in the body of iron and the other products of red cell destruction. Hemolytic anemia can be caused by defects in the red cell membrane, hemoglobinopathies (sickle cell disease or thalassemia), or inherited enzyme defects (G6PD deficiency). Acquired forms of hemolytic anemia are caused by agents extrinsic to the red blood cell, such as drugs, bacterial and other toxins, antibodies, and physical trauma. Iron deficiency anemia, which is characterized by decreased hemoglobin synthesis, can result from dietary deficiency, loss of iron through bleeding, or increased demands for red cell production. Vitamin B12 and folic acid deficiencies impair red cell production by interfering with DNA synthesis. Aplastic anemia is caused by bone marrow suppression and usually results in a reduction of white blood cells and platelets, as well as red blood cells. Chronic diseases such as inflammatory disorders (rheumatoid arthritis), cancers, and CKD cause anemia through the production of inflammatory cytokines that interfere with erythropoietin production or response.

**POLYCYTHEMIA**

After completing this section of the chapter, you should be able to meet the following objectives:

- Define the term polycythemia.
- Compare causes of polycythemia vera and secondary polycythemia.
- Describe the manifestations of polycythemia.

Polycythemia is an abnormally high total red blood cell mass with a hematocrit greater than 54% in men and greater than 47% in women. A hematocrit greater than 50% can cause cardiac dysfunction and vascular obstruction, while a hematocrit greater than 60% can lead to hypoxia. Polycythemia is categorized as relative or absolute. In relative polycythemia, also called Gaisbock syndrome, the hematocrit rises because of a loss of plasma volume without a corresponding decrease in red cells. This may occur with water deprivation, excessive diuretic usage, or gastrointestinal losses. Relative polycythemia is corrected by increasing the vascular fluid volume. Absolute polycythemia is a rise in hematocrit due to an increase in total red cell mass and is classified as primary or secondary.

**Absolute Polycythemia—Primary**

Primary polycythemia, or polycythemia vera, is a neoplastic disease of the pluripotent cells of the bone marrow characterized by an absolute increase in total red blood cell mass accompanied by elevated white cell and platelet counts. In polycythemia vera, the clinical manifestations are variable and are related to an increase in the red cell count, hemoglobin level, and hematocrit with increased blood volume and viscosity. Viscosity rises exponentially with the hematocrit and can interfere with cardiac output and blood flow. Hypertension is common and there may be complaints of headache, dizziness, inability to concentrate, and some difficulty with hearing and vision because of decreased cerebral blood flow. Venous stasis gives rise to a plethora appearance or dusky redness, even cyanosis, particularly of the lips, fingernails, and mucous membranes. Because of the increased concentration of blood cells, the person may experience itching and pain in the fingers or toes, and the hypermetabolism may induce night sweats and weight loss. Thromboembolism and hemorrhage, due to platelet abnormalities, are common complications that can be prevented by phlebotomy. The goal of treatment in primary polycythemia is to reduce blood viscosity. Withdrawing blood by periodic phlebotomy to reduce red cell volume can do this.

**Absolute Polycythemia—Secondary**

Secondary polycythemia results from a physiologic increase in the level of erythropoietin, commonly as a compensatory response to hypoxia. Conditions causing hypoxia include living at high altitudes, chronic heart and lung disease, and
smoking. Native people who live at high altitudes of 14,000 to 17,000 feet develop secondary polycythemia or physiologic polycythemia where their RBC count is generally 6 to 7 million/mm³. This allows them to perform all types of heavy labor at high altitude.³ The resultant release of erythropoietin by the kidney causes the increased formation of red blood cells in the bone marrow. Neoplasms that secrete erythropoietin may also cause a secondary polycythemia. Kidney disease such as hydronephrosis or renal cysts may obstruct blood flow, cause hypoxia, and lead to an increase in erythropoietin. Treatment of secondary polycythemia focuses on relieving hypoxia. For example, continuous low-flow oxygen therapy can be used to correct the severe hypoxia that occurs in some people with chronic obstructive pulmonary disease. This form of treatment is thought to relieve the pulmonary hypertension and polycythemia and to delay the onset of cor pulmonale.

**IN SUMMARY**

Polycythemia describes a condition in which the red blood cell mass is increased. It can present as a relative or absolute. Relative polycythemia results from a loss of vascular fluid and is corrected by replacing the fluid. Absolute polycythemia is further classified as a primary or secondary disorder. Absolute primary polycythemia, or polycythemia vera, is a proliferative disease of the bone marrow with an absolute increase in total red blood cell mass accompanied by elevated white cell and platelet counts. Absolute secondary polycythemia results from increased erythropoietin levels caused by hypoxic conditions such as chronic heart and lung disease. Many of the manifestations of polycythemia are related to increased blood volume and viscosity that lead to hypertension and stagnation of blood flow.

**AGE-RELATED CHANGES IN RED BLOOD CELLS**

After completing this section of the chapter, you should be able to meet the following objectives:

- Describe the function of hemoglobin F in the neonate and describe the red blood cell changes that occur during the early neonatal period.
- Cite the factors that predispose to hyperbilirubinemia in the infant.
- Describe the pathogenesis of hemolytic disease of the newborn.
- Compare conjugated and unconjugated bilirubin in terms of production of encephalopathy in the neonate.
- Explain the action of phototherapy in the treatment of hyperbilirubinemia in the neonate.
- State the changes in the red blood cells that occur with aging.

**Red Cell Changes in the Neonate**

At birth, changes in the red blood cell reflect the transition to extrauterine life and the need to transport oxygen from the lungs (Table 27.4). Hemoglobin concentrations at birth are high, reflecting the high synthetic activity in utero to provide adequate oxygen delivery. Toward the end of the first postnatal week, hemoglobin concentration begins to decline, gradually falling to a minimum value at approximately age 2 months. The red cell count and hematocrit likewise fall. The factors responsible for the decline include reduced red cell production and plasma dilution caused by increased blood volume with growth. Neonatal red cells also have a shorter life span of 50 to 70 days and are thought to be more fragile than those of older adults. During the early neonatal period, there is also a switch from HbF to HbA. The switch to HbA provides greater unloading of oxygen to the tissues because HbA has a lower affinity for oxygen compared with HbF. Infants who are small for gestational age or born to diabetic or smoking mothers or who experienced hypoxia in utero have higher total hemoglobin levels, higher HbF levels, and a delayed switch to HbA.

A physiologic anemia of the newborn develops at approximately 2 months of age. It seldom produces symptoms and cannot be altered by nutritional supplements. Anemia of prematurity, an exaggerated physiologic response in infants with low birth weight, is thought to result from a poor erythropoietin response. A contributing factor is the frequent blood sampling often required in these infants. The hemoglobin level rapidly declines after birth to a low of 7 to 10 g/dL at approximately 6 weeks of age. Signs and symptoms include apnea, poor weight gain, pallor, decreased activity, and tachycardia. In infants born before 33 weeks’ gestation or those with hematocrits below 33%, the clinical features are more evident.

Anemia at birth, characterized by pallor, congestive heart failure, or shock, is usually caused by hemolytic disease of the newborn. Bleeding from the umbilical cord, internal hemorrhage, congenital hemolytic disease, and frequent blood sampling are other possible causes of anemia. The severity of symptoms and presence of coexisting disease may warrant red cell transfusion.

**Hyperbilirubinemia in the Neonate**

Hyperbilirubinemia, an increased level of serum bilirubin, is a common cause of jaundice in the neonate. A benign, self-limited condition, it most often is related to the developmental state of the neonate. Rarely, cases of hyperbilirubinemia are pathologic and may lead to kernicterus and serious brain damage.

Physiologic jaundice appears in term infants on the 2nd or 3rd day of life. Ordinarily, the indirect bilirubin in umbilical cord blood is 1 to 3 mg/dL and increases by no more than 5 mg/dL in 24 hours, giving rise to jaundice. The increase in bilirubin is related to the increased red cell breakdown and the inability of the immature liver to conjugate bilirubin. Premature infants exhibit a slower rise and longer duration of serum bilirubin levels, perhaps because of poor hepatic uptake and reduced albumin binding of bilirubin. Peak bilirubin levels
of 8 to 12 mg/dL appear on days 5 to 7. Most neonatal jaundice resolves spontaneously within 1 week and is untreated.

The cause of jaundice is made on the basis of history and clinical and laboratory findings. Many factors cause elevated bilirubin levels in the neonate, including breast-feeding, hemolytic disease of the newborn, hypoxia, infections, and acidosis. Bowel or biliary obstruction and liver disease are less common causes. Associated risk factors include prematurity, Asian ancestry, and maternal diabetes. These neonates accumulate significant levels of unconjugated bilirubin 7 days after birth, with maximum levels of 10 to 30 mg/dL reached in the 3rd week of life. It is thought that the breast milk contains fatty acids that inhibit bilirubin conjugation in the neonatal liver. A factor in breast milk is also thought to increase the absorption of bilirubin in the duodenum. This type of jaundice disappears if breast-feeding is discontinued. Nursing can be resumed in 3 to 4 days without any hyperbilirubinemia ensuing.

Hyperbilirubinemia places the neonate at risk for the development of a neurologic syndrome called kernicterus. This condition is caused by the accumulation of unconjugated bilirubin in brain cells. Unconjugated bilirubin is lipid soluble, crosses the permeable blood–brain barrier of the neonate, and is deposited in cells of the basal ganglia, causing brain damage. Asphyxia and hyperosmolality may also contribute by damaging the blood–brain barrier and allowing bilirubin to cross and enter the cells. The level of unconjugated bilirubin and the duration of exposure that will be toxic to the infant are unknown. Symptoms may appear 2 to 5 days after birth in term infants or by day 7 in premature infants. Lethargy, poor feeding, and short-term behavioral changes may be evident in mildly affected infants. Severe manifestations include rigidity, tremors, ataxia, and hearing loss. Extreme cases cause seizures and death. Most survivors are seriously damaged and by 3 years of age exhibit involuntary muscle spasm, seizures, mental retardation, and deafness.

Hyperbilirubinemia in the neonate is treated with phototherapy or exchange transfusion. Phototherapy is more commonly used to treat jaundiced infants and reduce the risk of kernicterus. Exposure to fluorescent light in the blue range of the visible spectrum (420- to 470-nm wavelength) reduces bilirubin levels. Bilirubin in the skin absorbs the light energy and is converted to a structural isomer that is more water soluble and can be excreted in the stool and urine. Effective treatment depends on the area of skin exposed and the infant’s ability to metabolize and excrete bilirubin. Frequent monitoring of bilirubin levels, body temperature, and hydration is critical to the infant’s care. Exchange transfusion is considered when signs of kernicterus are evident or hyperbilirubinemia is sustained or rising and unresponsive to phototherapy.

**Hemolytic Disease of the Newborn**

Erythroblastosis fetalis, or hemolytic disease of the newborn, occurs in Rh-positive infants of Rh-negative mothers who have been sensitized. The mother can produce anti-Rh antibodies from pregnancies in which the infants are Rh positive or by blood transfusions of Rh-positive blood. The Rh-negative mother usually becomes sensitized during the first few days after delivery, when fetal Rh-positive red cells from the placental...
site are released into the maternal circulation. Because the antibodies take several weeks to develop, the first Rh-positive infant of an Rh-negative mother usually is not affected. Infants with Rh-negative blood have no antigens on their red cells to react with the maternal antibodies and are not affected.

After an Rh-negative mother has been sensitized, the Rh antibodies from her blood are transferred to subsequent infants through the placental circulation. These antibodies react with the red cell antigens of the Rh-positive infant, causing agglutination and hemolysis. This leads to severe anemia with compensatory hyperplasia and enlargement of the blood-forming organs, including the spleen and liver, in the fetus. Liver function may be impaired, with decreased production of albumin causing massive edema, called hydrops fetalis. If blood levels of unconjugated bilirubin are abnormally high because of red cell hemolysis, there is a danger of kernicterus developing in the infant, resulting in severe brain damage or death.

Several advances have served significantly to decrease the threat to infants born to Rh-negative mothers—prevention of sensitization, antenatal identification of the at-risk fetus, and intrauterine transfusion to the affected fetus. The injection of Rh immune globulin (i.e., gamma-globulin containing Rh antibody) prevents sensitization in Rh-negative mothers who have given birth to Rh-positive infants if administered at 28 weeks’ gestation and within 72 hours of delivery, abortion, genetic amniocentesis, or fetal–maternal bleeding. After sensitization has developed, the immune globulin is of no value. Since 1968, the year Rh immune globulin was introduced, the incidence of sensitization of Rh-negative women has dropped dramatically. Early prenatal care and screening of maternal blood continue to be important in reducing immunization. Efforts to improve therapy are aimed at production of monoclonal anti-D, the Rh antibody.

Exchange transfusions are administered after birth by removing and replacing the infant’s blood volume with type O Rh-negative blood. The exchange transfusion removes most of the hemolyzed red cells and some of the total bilirubin, treating the anemia and hyperbilirubinemia.

**Red Cell Changes With Aging**

Anemia is an increasingly common health problem in the elderly. It is known to increase with age, with the highest prevalence in men aged 85 years and older. Undiagnosed and untreated anemia can have severe complications and is associated with increased risk of mortality.

Hemoglobin levels decline after middle age. In studies of men older than 60 years of age, mean hemoglobin levels ranged from 15.3 to 12.4 g/dL, with the lowest levels found in the oldest adults. The decline is less in women. In most asymptomatic older adults, lower hemoglobin levels result from iron deficiency and anemia of chronic disease caused by inflammatory disease, malignancy, or CKD.

As with other body systems, the capacity for red cell production changes with aging. The location of bone cells involved in red cell production shifts toward the axial skeleton, and the number of progenitor cells declines. Despite these changes, older adults are able to maintain hemoglobin and hematocrit levels within a range similar to that of younger adults. However, during a stress situation such as bleeding, the red blood cells of older adults are not replaced as promptly as those of their younger counterparts. This inability to replace red blood cells closely correlates with the increased prevalence of anemia in older adults.

Inflammatory cytokines, which have been found to increase with age, may mediate this reduced sensitivity to erythropoietin.

The diagnosis of anemia in older adults requires a complete physical examination, a CBC, and studies to rule out comorbid conditions such as malignancy, gastrointestinal conditions that cause bleeding, and pernicious anemia. The CBC should include a peripheral blood smear and a reticulocyte count and index. The treatment of anemia in older adults should focus on the underlying cause and correction of the red cell deficit. Although erythropoietin remains the treatment of choice for anemias associated with cancer and renal disease, its potential complications especially regarding cardiovascular disease remain to be established.

**IN SUMMARY**

Hemoglobin concentrations at birth are high, reflecting the in utero need for oxygen delivery. Toward the end of the first postnatal week, these levels begin to decline, gradually falling to a minimum value at approximately 2 months of age. During the early neonatal period, there is a shift from fetal to HbA. Many infants have physiologic jaundice because of hyperbilirubinemia during the first week of life, probably related to increased red cell breakdown and the inability of the infant’s liver to conjugate bilirubin. The term kernicterus describes elevated levels of lipid-soluble, unconjugated bilirubin, which can be toxic to brain cells. Depending on severity, kernicterus is treated with phototherapy or exchange transfusions (or both). Hemolytic disease of the newborn occurs in Rh-positive infants of Rh-negative mothers who have been sensitized. It involves hemolysis of infant red cells in response to maternal Rh antibodies that have crossed the placenta. Administration of Rh immune globulin to the mother within 72 hours of delivery of an Rh-positive infant, abortion, or amniocentesis prevents sensitization.

Anemia is an increasingly common health problem in older adults. With the increasing numbers of older adults, this will become more of a health care challenge. As with many other tissue cells, the capacity for red cell replacement decreases with aging. Although most older adults are able to maintain their hemoglobin and hematocrit levels within a normal range, they are unable to replace their red cells as promptly as their younger counterparts during a stress situation such as bleeding. This inability to replace red blood cells closely correlates with the increased prevalence of anemia in older adults, which is usually the result of bleeding, infection, malignancy, or chronic disease.
A 29-year-old woman complains of generalized fatigue. Her physical examination reveals a heart rate of 115 beats/minute, blood pressure 115/75, and respiratory rate of 28 breaths/minute. Her skin and nail beds are pale. Her laboratory results include red blood cell count 3.0 × 10^6/µL, hematocrit 30%, hemoglobin 9 g/dL, and a decrease in serum ferritin levels.

A. What disorder do you suspect this woman has?
B. What additional data would be helpful in determining the etiology of her condition?
C. Which of her signs reflect the body’s attempt to compensate for the disorder?
D. What is the significance of the low ferritin level, and how could it be used to make decisions related to her treatment?

A 65-year-old woman is being seen in the clinic because of numbness in her lower legs and feet and difficulty walking. She has no other complaints. She takes a blood pressure pill, two calcium pills, and a multivitamin pill daily. Her laboratory results include red blood cell count 3.0 × 10^6/µL, hematocrit 20%, hemoglobin 9 g/dL, and a markedly elevated MVC.

A. What type of anemia does she have?
B. What is the reason for her neurologic symptoms?
C. What type of treatment would be appropriate?

A 12-year-old boy with sickle cell disease presents in the emergency department with severe chest pain. His mother reports that he was doing well until he came down with a respiratory tract infection. She also states he insisted on playing basketball with the other boys in the neighborhood even though he wasn’t feeling well.

A. What is the most likely cause of pain in this boy?
B. Infections and aerobic-type exercise that increase the levels of deoxygenated hemoglobin produce sickling in people who are homozygous for the sickle cell gene and have sickle cell disease, but not in people who are heterozygous and have sickle cell trait. Explain.
C. People with sickle cell disease experience anemia but not iron deficiency. Explain.

The white blood cells and lymphoid tissues where these cells originate and mature function to protect the body against invasion by foreign agents. Disorders of the white blood cells include leukopenia, in which there is a deficiency in leukocytes, and proliferative disorders, in which there is an expansion of leukocytes. The proliferative disorders may be reactive, as occurs with infection, or neoplastic, as occurs with malignant lymphomas and leukemia. This chapter focuses on leukopenia, infectious mononucleosis, malignant lymphomas, leukemias, and plasma cell dyscrasias (multiple myeloma).

The hematopoietic system encompasses all the blood cells and their precursors. It includes the myeloid or bone marrow tissue, in which the blood cells are formed, and the lymphoid tissues of the lymph nodes, thymus, and spleen, in which the white blood cells circulate, mature, and function. The development of the different blood cells involves interactions among precursor bone marrow cells and a variety of growth factors, cytokines (chemical messengers), and gene products such as transcription factors.
Leukocytes (White Blood Cells)

The white blood cells include the granulocytes (i.e., neutrophils, eosinophils, and basophils), monocytes/macrophages, and lymphocytes. The granulocytes and the agranular monocytes/macrophages are derived from the myeloid stem cell in the bone marrow and circulate in the blood (Fig. 28.1).

The T lymphocytes (T cells) and B lymphocytes (B cells) originate from lymphoid stem cells in the bone marrow and migrate between the blood and the lymphatic system. T lymphocytes mature in the thymus, and B lymphocytes in the bone marrow—the mammalian equivalent of the avian bursa of Fabricius. The T lymphocytes differentiate to form CD4+ helper T cells, which serve to orchestrate the immune response, and CD8+ cytotoxic T cells, which provide for cell-mediated immune responses. The B lymphocytes differentiate to form immunoglobulin-producing plasma cells. Another population of lymphocytes includes the large granular lymphocytes, or natural killer (NK) cells, which do not share the specificity or characteristics of the T or the B lymphocytes but have the ability to lyse target cells.

Bone Marrow and Hematopoiesis

The entire hematopoietic system, with all its complexity, arises from a small number of stem cells that differentiate to form blood cells and replenish the bone marrow by a process of self-renewal. All the hematopoietic precursors, including the erythroid (red blood cell), myelocyte (granulocyte and monocyte), lymphocyte (T cell and B cell), and megakaryocyte (platelet) series, are derived from a small population of cells called pluripotent stem cells (Fig. 28.2). These cells are capable of providing progenitor cells (i.e., parent cells) for myelopoiesis and lymphopoiesis, processes by which myeloid and lymphoid blood cells are made. Several levels of differentiation lead to the development of committed unipotent cells, which are the progenitors for each of the different blood cell types.

Hematopoietic Growth Factors

Like erythropoiesis, leukopoiesis, or production of white blood cells, is controlled by hematopoietic growth factors. The hematopoietic growth factors are a family of glycoproteins that support hematopoietic colony formation. These growth factors can be categorized into three groups: the growth factors that are involved in the development of a specific cell lineage; those that affect the early multipotent progenitor cells; and those that induce the expression of growth factor genes in other cells. Cytokines or chemical messengers, such as interleukin (IL)-1, IL-4, IL-6, and interferon, act synergistically to support the functions of the growth factors.

There are several lineage-specific growth factors: erythropoietin, granulocyte–macrophage colony-stimulating factor (GM-CSF), and monocyte–macrophage colony-stimulating factor (M-CSF). Although the hematopoietic growth factors act at different points in the proliferation and differentiation pathway, their functions overlap. For example, GM-CSF stimulates the growth and function of granulocyte, macrophage, and eosinophil progenitor cells and induces IL-1 gene expression in neutrophils and peripheral mononuclear leukocytes. Cytokines, such as IL-3, act on the most immature bone marrow progenitor.
cells, thereby promoting the development of cells that can differentiate into a number of cell types. The identification and characterization of the various growth factors and cytokines have led to their use in treating a wide range of diseases, including bone marrow failure, hematopoietic neoplasms, infectious diseases, and congenital and myeloproliferative disorders.

**Leukocyte Developmental Stages**

Leukocyte development begins with the myeloid and lymphoid stem cells in the bone marrow. The granulocyte and monocyte cell lines derive from the myeloid stem cells and the lymphocytes from the lymphoid stem cells (see Fig. 28.1). The immature precursor cells for each of the cell lines are called blast cells. Myeloblasts, which are the granulocytic precursor cells, have round to oval nuclei, with delicate chromatin and a blue to gray cytoplasm. During the next stage of development, the myeloblasts are transformed into promyelocytes with similar nuclei, but with a cytoplasm containing many primary granules. In the subsequent metamyelocyte stage, the nuclei distort and become arclike, producing the band developmental stage. Maturation from metamyelocyte to mature neutrophil involves progressive condensation of nuclear chromatin, increasing nuclear lobulation, and the appearance of secondary (specific) granules. Eosinophils and basophils undergo similar developmental stages but develop different secondary granules. Like granulocytes, monocytes develop from the granulocyte–monocyte progenitor cell and progress through a monoblast and promonocyte stage. By contrast, lymphocytes derive from lymphoid stem cells and progress through the lymphoblast and prolymphocyte stages. The prolymphocytes leave the bone marrow and travel to the lymphoid tissues, where further differentiation into T and B lymphocytes occurs. The names of the various leukocyte developmental stages are often used in describing blood cell changes that occur in hematopoietic disorders (e.g., acute lymphoblastic leukemia [ALL], acute promyelocytic leukemia).
FIGURE 28.3  •  The lymph tissue. The lymph nodes, spleen, and thymus are all part of the lymphatic system. (From Moore K. L., Agur A. M., & Dalley A. F. (2011). Essential clinical anatomy (4th ed., p. 29, Fig. 1-17A). Philadelphia, PA: Wolters Kluwer/Lippincott Williams & Wilkins.)
KEY POINTS

HEMATOPOIESIS

• The white blood cells are formed from hematopoietic stem cells that differentiate into committed progenitor cells that in turn develop into the myelocytic and lymphocytic lineages needed for the formation of the different types of white blood cell.
• The life span of white blood cells is relatively short so that constant renewal is necessary to maintain normal blood levels. Any conditions that decrease the availability of stem cells or hematopoietic growth factors produce a decrease in white blood cells.

Lymphoid Tissues

The body’s lymphatic system consists of the lymphatic vessels, lymphoid tissue and lymph nodes, thymus, and spleen (Fig. 28.3). Although both precursor B and T lymphocytes begin their development in the bone marrow, they migrate to peripheral lymphoid structures to complete the differentiation process. B lymphocytes leave the bone marrow, differentiate into plasma cells, and then move to the lymph nodes, where they continue to proliferate and produce antibodies. T lymphocytes leave the bone marrow as precursor T lymphocytes travel to the thymus, where they differentiate into CD4+ helper T cells and CD8+ cytotoxic T cells, after which many of them move to lymph nodes, where they undergo further proliferation.

Lymph nodes, which are the site where many lymphomas originate, consist of organized collections of lymphoid tissue located along the lymphatic vessels. Typically grayish-white and ovoid or bean-shaped, they range in size from 1 mm to about 1 to 2 cm in diameter. A fibrous capsule and radiating trabeculae provide a supporting structure, and a delicate reticular network contributes to internal support (Fig. 28.4). The parenchyma of the lymph node is divided into an outer or superficial cortex and an inner medulla. The superficial cortex contains well-defined B-cell and T-cell domains. The B-cell–dependent cortex consists of two types of follicles: immunologically inactive follicles, called primary follicles, and active follicles that contain germinal centers, called secondary follicles. Germinal centers contain large lymphocytes (centroblasts) and small lymphocytes with cleaved nuclei (centrocytes). The mantle zone is the small layer of B cells surrounding the germinal centers. The portion of the cortex between the medullary and superficial cortex is called the paracortex. This region contains most of the T cells in the lymph nodes.
lines are called blast cells. The blast cells progress through subsequent maturational stages before becoming mature granulocytes, monocytes, or lymphocytes. The names of these developmental stages are often used in describing blood cell changes that occur in hematopoietic disorders.

The lymphatic system consists of a network of lymphatic vessels, nodes, and tissues where B and T lymphocytes complete their differentiation. Lymph nodes, which are the site where many lymphomas originate, exhibit an outer or superficial cortex and an inner medulla. The cortex contains well-defined B-cell and T-cell domains. The B-cell–dependent cortex consists of two types of follicles: immunologically inactive follicles, called primary follicles, and active follicles that contain germinal centers, called secondary follicles. Most of the T cells are contained in the paracortex, the area between the medullary and superficial cortices.

Although some lymphocytes enter the lymph nodes through the afferent lymphatic channels, most enter through the wall of postcapillary venules located in the deep cortex. These vessels, which are lined with specialized endothelial cells that possess receptors for antigen-primed lymphocytes, signal lymphocytes to leave the circulation and migrate through the lymph nodes. Both B and T cells leave the bloodstream through these channels. The T cells remain in the paracortex and the B cells migrate to the follicular area of the cortex. Most lymphocytes leave the lymph node by entering the lymphatic sinuses, from which they enter the efferent lymphatic vessel.

The alimentary canal, respiratory passages, and genitourinary systems are guarded by accumulations of lymphoid tissue that are not enclosed in a capsule. This form of lymphoid tissue is called diffuse lymphoid tissue or mucosa-associated lymphoid tissue (MALT) because of its association with mucous membranes (Fig. 28.5). Lymphocytes are found in the subepithelium of these tissues. Lymphomas can arise from MALT as well as lymph node tissue.

**IN SUMMARY**

Leukocyte or white blood cell development begins with the myeloid and lymphoid stem cells in the bone marrow. The granulocyte and monocyte cell lines derive from the myeloid stem cells, and lymphocytes from the lymphoid stem cells. The immature precursor cells for each of the cell lines are called blast cells. The blast cells progress through subsequent maturational stages before becoming mature granulocytes, monocytes, or lymphocytes. The names of these developmental stages are often used in describing blood cell changes that occur in hematopoietic disorders.
The ANC is supposed to be 1000/µL, and if the ANC is less than 500 cells/mm³, the person is generally put on neutropenic precautions in the hospital to protect him or her from the environment.⁸

Neutropenia refers specifically to an abnormally low number of neutrophils and is commonly defined as a circulating neutrophil count of less than 1000/µL. Agranulocytosis denotes a virtual absence of neutrophils. In aplastic anemia, the individual will have a depletion of all of the myeloid stem cells resulting in anemia, thrombocytopenia, and agranulocytosis. When all of the red blood cells, white blood cells, and platelets are considerably low, it is referred to as pancytopenia.

Neutropenia can result from decreased neutrophil production, accelerated utilization or destruction, or a shift from the blood to the tissue compartments. It can be present at birth (congenital) or arise from a number of factors that occur later in life and do not have a hereditary component (acquired).

### Congenital Neutropenia

Inherited disorders of proliferation and maturation of myeloid stem cell lines are relatively rare. Two of the more severe inherited types of congenital neutropenia are cyclic neutropenia and severe congenital neutropenia.⁷,⁸ There are also several congenital immunodeficiency disorders that are accompanied by severe neutropenia, including the severe combined immunodeficiencies and common variable immunodeficiency. In addition to the inherited forms of neutropenia that present in infancy, an alloimmune neonatal neutropenia can occur because of the transplacental transfer of maternal antibodies.

Alloimmune neonatal neutropenia is neutropenia that occurs after transplacental transfer of maternal alloantibodies directed at an infant’s neutrophils, analogous to Rh hemolytic disease. The disorder usually involves phagocytic destruction of antibody-coated neutrophils by splenic macrophages. Affected infants may present with delayed separation of the umbilical cord, mild skin infection, fever, and pneumonia within the first 2 weeks of life.

Periodic or cyclic neutropenia is a rare autosomal dominant disorder with variable expression that begins in infancy and persists for decades. The disorder arises from a regulatory abnormality involving early hematopoietic precursors and is associated with the neutrophil elastase (a protease that degrades virulent factors in bacteria) gene.⁷ It is characterized by regular, periodic oscillations of peripheral neutrophils from normal to neutropenic values every 18 to 24 days.⁷ During the neutropenic periods, most people suffer from fever, stomatitis, and pharyngitis, occasionally associated with lymph node enlargement. Serious infections may occur occasionally. The cycles often become less noticeable in older adults, and the disorder then begins to resemble that of chronic neutropenia.

Severe congenital neutropenia, or Kostmann syndrome, is characterized by an arrest in myeloid maturation at the promyelocyte stage of development that can be inherited as either an autosomal dominant or autosomal recessive trait.¹⁰ The autosomal dominant disease is usually associated with mutations in the neutrophil elastase gene, which in turn leads to apoptosis of bone marrow myeloid cells. The autosomal recessive severe congenital neutropenia or Kostmann syndrome is due to mutations in the HAX-1 gene, which causes a loss of mitochondrial potential.¹⁰ The disorder is characterized by severe bacterial infections. Before the GM-CSFs became available for clinical use, two thirds of children died of fatal infections before reaching adolescence. Approximately 20% of people with the disorder develop acute myelogenous leukemia (AML).¹⁰

### Acquired Neutropenia

Acquired neutropenia encompasses a broad spectrum of causative processes and includes primary and secondary autoimmune neutropenia, infection-related neutropenia, and drug-induced neutropenia (Chart 28.1). It also may be caused by a number of bone marrow disorders, hematopoietic malignancies, and radiation therapy.

#### Autoimmune Neutropenia

Autoimmune neutropenia results from antibodies directed against neutrophil cell membrane antigens or bone marrow progenitors. The autoimmune forms

### Chart 28.1 PRINCIPAL CAUSES OF NEUTROPENIA

**Congenital**
- Alloimmune neonatal neutropenia (transfer of maternal antibodies)
- Cyclic neutropenia
- Kostmann syndrome (severe congenital neutropenia)

**Acquired**

**Autoimmune**
- Primary (rare, usually occurs in children and runs a benign course)
- Secondary
  - Systemic lupus erythematosus
  - Felty syndrome in people with RA
- Infection related
  - Many types of infections agents, but most commonly viruses
- Mechanisms include increased consumption of neutrophils, production of autoantibodies, direct infiltration of hematopoietic cells, bone marrow suppression

**Drug related**
- Immune-mediated reactions in which drugs act as hapten (e.g., penicillin, propylthiouracil, aminopyrine)
- Accelerated apoptosis (clozapine [antipsychotic agent])
- Cancer chemotherapeutic drugs (bone marrow depression)
- Radiation therapy to bone marrow

Hematologic malignancies
of neutropenia may be classified as primary (i.e., those not associated with other detectable pathologic processes) or secondary (i.e., those associated with another disease condition). Primary autoimmune neutropenia is a rare disorder of early childhood, during which a moderate to severe neutropenia is observed. The condition is usually benign, with mild to moderate infections for children. The disorder is rare in adults. Because primary autoimmune neutropenia is self-limiting, treatment is usually restricted to the use of antimicrobial agents for people who experience recurrent infections.

Secondary immune-associated neutropenia is often associated with systemic autoimmune disorders, mainly rheumatoid arthritis (RA) and systemic lupus erythematosus (SLE). Felty syndrome, a variant of RA, is a triad of splenomegaly, recurrent pulmonary infections, and neutropenia. The neutropenia is the result of antineutrophil antibodies and high levels of circulating immune complexes, which induce neutrophil apoptosis. Coupled with the end-organ manifestations of RA, the majority of people with Felty syndrome are susceptible to serious bacterial infection that sometimes leads to sepsis and poor clinical outcome.

Several antibody-mediated mechanisms are believed to be responsible for the neutropenia seen in people with SLE. These include the development of antineutrophil antibodies, along with increased neutrophil apoptosis and decreased neutrophil production by the bone marrow. Similar to Felty syndrome, continued treatment of SLE to control symptoms is the preferred method of treatment.

Infection-Related Neutropenia. Many different types of infectious diseases, including viral, bacterial, rickettsial, and parasitic, may cause neutropenia, the most common being viral. Infections may produce neutropenia in multiple ways such as decreased neutrophil production, loss of neutrophils by toxins, or problems resulting in neutrophil sequestration in the spleen. Neutropenia is also a common manifestation of acquired immunodeficiency syndrome (AIDS), in which a virus-induced suppression of marrow cell proliferation is often aggravated by infectious consumption of neutrophils and by antiviral drugs.

Drug-Related Neutropenia. The incidence of drug-induced neutropenia has increased significantly over the last several decades and is attributed primarily to a wider use of drugs in general and more specifically to the use of chemotherapeutic drugs in the treatment of cancer. People with almost any malignancy who receive chemotherapy with or without radiation therapy and also biotherapy are at risk for development of chemotherapy-induced neutropenia. The risk for development of chemotherapy-induced neutropenia is influenced by patient- and treatment-related disease, oncological disease, and other comorbidities. One of the most important patient-related factors is age. Older adults are at greater risk than younger people because of age-related cellular changes in neutrophils. People who have kidney disease, other comorbidities, and poor hydration and nutrition are also at great risk for neutropenia. Disease-related factors include neoplastic bone involvement, type of cancer, and history of anemia or neutropenia with prior chemotherapy regimens. Treatment-related factors include radiation therapy to the bone marrow, extensive prior chemotherapy, and treatment regimen.

The term idiosyncratic is used to describe drug reactions that are different from the effect obtained in most people and that cannot be explained in terms of allergy. A number of idiosyncratic cases of drug-induced neutropenia are thought to be caused by immunologic mechanisms, with the drug or its metabolites acting as antigens (i.e., haptons) to incite the production of antibodies reactive against neutrophils. In the case of hapten formation, discontinuation of the drug usually results in resolution of neutropenia within a week or two. Some drugs, such as the antipsychotic drug clozapine, have been shown to cause accelerated apoptosis of neutrophils. Clozapine has been shown to cause agranulocytosis in a small but significant number of people. The reaction is reversible on discontinuation of the drug. Because of the risk of agranulocytosis, people receiving clozapine must have weekly blood counts done for the first 6 months of therapy.

Other drugs, such as the β-lactam antibiotics (e.g., cephalosporins), particularly when given in high doses, and some anticonvulsant drugs (e.g., carbamazepine) may inhibit the colony-forming units of granulocytes and monocytes–macrophages in bone marrow. Suppression of myeloid precursors in the bone marrow also has been noted with administration of ticlopidine (an antiplatelet drug), sulfasalazine, and chlorpromazine (an antipsychotic drug). The clinical features of neutropenia usually depend on the severity of neutropenia and the cause of the disorder. Neutropenia from any cause increases the risk for infection by gram-positive and gram-negative bacteria and fungi.

Neutrophils provide the first line of defense against organisms that inhabit the skin and gastrointestinal tract. Thus early signs of infection due to neutropenia, particularly those associated with a mild to moderate decrease in neutrophils, include mild skin lesions, stomatitis, pharyngitis, and diarrhea. Signs and symptoms of more severe neutropenia include malaise, chills, and fever, followed in sequence by marked weakness and fatigability. Untreated infections can be rapidly fatal, particularly if the ANC drops below 250/µL. With severe neutropenia, the usual signs of infection may not be present because of a lack of a sufficient number of neutrophils to produce an inflammatory response.

Antimicrobial agents are used to treat infections in situations in which neutrophil destruction cannot be controlled or the neutropoietic function of the bone marrow cannot be recovered. Hematopoietic growth factors such as recombinant human granulocyte CSF (filgrastim, pegfilgrastim) may be used to stimulate the maturation and differentiation of the granulocyte cell lineage. In people receiving chemotherapy...
Infectious Mononucleosis

Infectious mononucleosis is a self-limiting lymphoproliferative disorder. Eighty-five percent of the time it is caused by the Epstein-Barr virus (EBV), a member of the herpesvirus family. The term EBV-associated infectious mononucleosis is often used to designate infectious mononucleosis caused by EBV as opposed to non–EBV-associated clinical syndromes of infectious mononucleosis caused by other agents, such as cytomegalovirus, Hepatitis A, human immunodeficiency virus (HIV), and rubella. Infectious mononucleosis may occur at any age but occurs principally in adolescents and young adults in developed countries. In areas of the world where children often live in crowded conditions, asymptomatic infection with EBV occurs in childhood and infectious mononucleosis is not encountered.

EBV spreads from person to person primarily through contact with infected oral secretions. Transmission requires close contact with infected people. Thus, the virus spreads readily among young children in crowded conditions, where there is considerable sharing of oral secretions.

Pathogenesis

EBV initially penetrates the nasopharyngeal, oropharyngeal, and salivary epithelial cells. It then spreads to the underlying oropharyngeal lymphoid tissue and, more specifically, to B lymphocytes, all of which have receptors for EBV. Infection of the B cells may take one of two forms—it may kill the infected B cell, or the virus may incorporate itself into the cell’s genome. The B cells that harbor the EBV genome proliferate in the circulation and produce the well-known heterophil antibodies that are used for the diagnosis of infectious mononucleosis. A heterophil antibody is an immunoglobulin that reacts with antigens from another species—in this case, sheep red blood cells.

The normal immune response is important in controlling the proliferation of the EBV-infected B cells and cell-free virus. Most important in controlling the proliferation of EBV-infected B cells are the CD8+ cytotoxic T cells and NK cells. These virus-specific T cells appear as large, atypical lymphocytes that are characteristic of the infection (Fig. 28.6). In otherwise healthy people, the humoral and cellular immune responses serve to control viral shedding by limiting the number of infected B cells rather than eliminating them.

Although infected B cells and free virions disappear from the blood after recovery from the disease, the virus remains in a few transformed B cells in the oropharyngeal region and is shed in the saliva. Once infected with the virus, people remain asymptptomatically infected for life, and a few such people intermittently shed EBV. Immunosuppressed people shed the virus more frequently. Asymptomatic shedding of EBV by healthy people is thought to account for most of the spread of infectious mononucleosis, despite the fact that it is not a highly contagious disease.

Clinical Course

The onset of infectious mononucleosis usually is insidious. The incubation period lasts 4 to 8 weeks. A prodromal period, which lasts for several days, follows and is characterized by malaise, anorexia, and chills. The prodromal period precedes the onset of fever, pharyngitis, and lymphadenopathy. Occasionally, the disorder comes on abruptly with a high fever. Most people seek medical attention for severe pharyngitis, which usually is most severe on days 5 to 7 and persists for 7 to 14 days. The lymph nodes are typically enlarged throughout the body, particularly in the cervical, axillary, and groin areas. Hepatitis and splenomegaly are common manifestations of the disease and are thought to be immune-mediated. Hepatitis is characterized by hepatomegaly, nausea, anorexia, and jaundice. Although discomforting, it usually is a benign condition that resolves without causing permanent liver damage. The spleen may be enlarged two to three times its normal size, and rupture of the spleen is an infrequent complication. In less than 1% of cases, mostly in the adult age group, complications of the central nervous system (CNS) develop. These complications include cranial nerve palsies, encephalitis, meningitis, transverse myelitis, and Guillain-Barré syndrome.

The peripheral blood usually shows an increase in the number of leukocytes, with a white blood cell count of 10,000 cells/µL, 30% of which are lymphocytes. The rise in white blood cells begins during the first week, continues during the 2nd week of the infection, and then returns to normal around the 4th week. Although leukocytosis is common, leukopenia may be seen in some persons during the first 3 days of illness. Atypical lymphocytes are common,
constituting more than 20% of the total lymphocyte count. Heterophil antibodies usually appear during the 2nd or 3rd week and decline after the acute illness has subsided. They may, however, be detectable for up to 12 months after onset of the disease.22

Most people with infectious mononucleosis recover without incident. The acute phase of the illness usually lasts for 2 to 3 weeks, after which recovery occurs rapidly. Some degree of debility and lethargy may persist for 2 to 3 months. Treatment is primarily symptomatic and supportive.

In people with immunodeficiency disorders that lead to defects in cellular immunity (e.g., HIV infection, immunosuppressant-treated recipients of organ or bone marrow transplants), EBV infection may contribute to the development of lymphoproliferative disorders (e.g., Hodgkin or non-Hodgkin lymphoma).23 These people have impaired T-cell immunity and are unable to control the proliferation of EBV-infected B cells.

IN SUMMARY

Neutropenia, which represents a marked reduction in the absolute number of neutrophils, is one of the major disorders of the white blood cells. It can occur as a congenital or acquired disorder. Congenital neutropenia consists primarily of cyclic neutropenia, which is characterized by cyclic (18- to 24-day) oscillations of peripheral neutrophils, and severe congenital neutropenia or Kostmann syndrome, which is associated with severe bacterial infections. The acquired neutropenias encompass a wide spectrum of causative processes, including immunologically mediated bone marrow suppression or neutrophil injury and destruction; infection-mediated mechanisms, including increased peripheral utilization; and drug-mediated mechanisms, particularly those related to the use of cancer chemotherapeutic agents. Neutropenia may also be caused by a number of bone marrow conditions, hematopoietic malignancies, and radiation therapy. Because the neutrophil is essential to host defenses against bacterial and fungal infections, severe and often life-threatening infections are common in people with neutropenia.

Infectious mononucleosis is a self-limited lymphoproliferative disorder caused by the B-lymphotropic EBV, a member of the herpesvirus family. The highest incidence of infectious mononucleosis is found in adolescents and young adults, and it is seen more frequently in the upper socioeconomic classes of developed countries. The virus is usually transmitted in the saliva. The disease is characterized by fever, generalized lymphadenopathy, sore throat, and the appearance in the blood of atypical lymphocytes and several antibodies, including the well-known heterophil antibodies that are used in the diagnosis of infectious mononucleosis. Most people with infectious mononucleosis recover without incident. Treatment is largely symptomatic and supportive.

The neoplastic disorders of lymphoid origin represent the most important of the white blood cell disorders. The neoplasia of lymphoid origin can arise from both B and T cells as well as tumors representing various stages of lymphocyte development.20 The major categories include non-Hodgkin lymphomas (NHLs), Hodgkin lymphoma (HL), lymphoid leukemias, and plasma cell dyscrasias. The clinical features of these neoplasms are largely determined by their cell of origin, the progenitor cell from which they originated, and the molecular events involved in their transformation into a malignant neoplasm. Because blood cells circulate throughout the body, these neoplasms are often disseminated from the onset.

Malignant Lymphomas

The lymphomas are a diverse group of solid tumors composed of neoplastic lymphoid cells that vary with respect to molecular features, genetics, clinical presentation, and treatment. Approximately 8830 new cases of HLs were diagnosed in the United States in 2011, of which about 1300 died. The incidence of NHL has increased with 66,360 new cases and 19,320 deaths in 2011 in the United States.21 Since the early 1970s the incidence rates for NHL have nearly doubled. Children are not as likely to be diagnosed with NHL. However, there were still approximately 500 new cases of NHL in children up to age 14 and 800 new HL cases in children up to 19 years of age.24

Non-Hodgkin Lymphomas

The NHLs represent a clinically diverse group of B-cell, T-cell, or NK-cell origin. They represent about 4% of all new cases of cancer diagnosed in the United States.25 As with most other malignancies, the cause of NHL is largely unknown. However, impairment of the immune system and infectious agents may play a role. There is evidence of EBV infection in essentially all people with Burkitt lymphoma, which is endemic to some parts of Africa.26 A second virus, the human T-cell lymphotropic virus (HTLV-1), which is endemic in the southwestern islands of Japan, has been associated with adult T-cell leukemia/lymphoma.4 The NHLs
are also seen with increased frequency in people infected with HIV, in those who have received chronic immunosuppressive therapy after organ transplantation, and in people with acquired or congenital immunodeficiencies. There is also a reported association between chronic Helicobacter pylori infection and low-grade MALT lymphoma of the stomach.

Although the NHLs can originate in any of the lymphoid tissues, they most commonly originate in the lymph nodes. Like normal lymphocytes, transformed B and T cells tend to home in to particular lymph node sites, leading to characteristic patterns of involvement. For example, B-cell lymphomas tend to proliferate in the B-cell areas of the lymph node, whereas T-cell lymphomas typically grow in the paracortical T-cell areas. All have the potential to spread to various lymphoid tissues throughout the body, especially the liver, spleen, and bone marrow.

The classification of NHLs have been classified by the World Health Organization (WHO) to include B-cell neoplasms, which include myelomas and leukemias that originate from B-cells, T-cell neoplasms, and NK-cell neoplasms. The NHLs are actually a complex group, based on the appearance of the lymphoma cells, the presence of surface markers (e.g., antigens, CD markers), and genetic features. Neoplasms of immature B cells include lymphoblastic leukemia/lymphoma (i.e., ALL). In addition, the specific types of lymphomas are sometimes grouped together into low-grade, aggressive, and very aggressive categories.

Mature B-Cell Lymphomas. Mature (peripheral) B-cell lymphomas are the most common type of lymphoma in the Western world. The most common of the mature B-cell lymphomas are the follicular lymphomas (22%) and diffuse large B-cell lymphomas (31%). Small lymphocytic lymphoma, mantle cell lymphoma, peripheral T-cell lymphoma, and MALT lymphoma together account for 28% of NHLs.

Follicular lymphomas are derived from germinal center B cells and consist of a mixture of centroblasts and centrocytes (Fig. 28.7). Follicular lymphomas are a particularly common neoplasm in the United States, where they constitute about one third of all adult NHLs, with a peak incidence at 60 years of age. The lymphoma predominantly affects lymph nodes. Other sites of involvement include the spleen, bone marrow, peripheral blood, head and neck region, gastrointestinal tract, and skin. Over time, approximately one of three follicular lymphomas transforms into a fast-growing diffuse large B-cell lymphoma.

Diffuse large B-cell lymphomas are a heterogeneous group of aggressive germinal or postgerminal center neoplasms. The disease occurs in all age groups but is most prevalent between 60 and 70 years of age. The cause of diffuse large B-cell lymphoma is unknown but may involve EBV or HIV infections. It is a rapidly evolving, multifocal, nodal and extranodal tumor. Manifestations are typically seen at the time of presentation. As a group, diffuse large B-cell lymphomas are rapidly fatal if untreated.

Burkitt lymphoma, one of the most rapidly growing tumors of the NHLs, is also a disorder of germinal center B cells. Endemic Burkitt lymphoma is the most common childhood cancer (peak age 3 to 7 years) in Central Africa, often beginning in the jaw. It occurs in regions of Africa where both EBV and malarial infection are common. Virtually 100% of people with African Burkitt lymphoma have evidence of previous EBV infection.

Mantle cell lymphomas constitute less than 10% of NHLs and have their origin in the naive B cell. After the precursor stage, B cells undergo immunoglobulin (Ig) gene rearrangements and develop into surface IgM- and IgD-positive naïve B cells. These cells give rise to mantle cell lymphoma. Mantle cell lymphomas do not occur in children, but affect older people (median age, 60 years). They have a rapid rate of progression, and half of people do not tend to survive 3 years.

Marginal zone lymphomas involve late-stage memory B cells that reside in the marginal zone or outermost compartment of the lymph node follicle. Variants of marginal node lymphoma include splenic marginal zone lymphoma and MALT lymphomas of the stomach and other mucosal surfaces. MALT lymphomas constitute 5% to 10% of all B-cell NHLs. Most MALT lymphomas involve the stomach or other mucosal sites, including the respiratory system. MALT lymphomas tend to remain localized for prolonged periods and to follow an indolent course. Extranodal marginal B cell lymphomas of the MALT type are curable by radiation or surgery when localized. MALT lymphomas that occur in the stomach secondary to H. pylori infection often respond to treatment with appropriate antimicrobial agents.

Clinical Manifestations. The manifestations of NHL depend on lymphoma type (i.e., indolent or aggressive) and the stage of the disease. People with indolent or slow-growing lymphomas usually present with painless lymphadenopathy, which may be isolated or widespread. Involved lymph nodes may be present in the retroperitoneum, mesentery, and pelvis. The indolent lymphomas are usually disseminated at the time of diagnosis, and bone marrow involvement is frequent.
With or without treatment, the natural course of the disease may fluctuate over 5 to 10 or more years. Many low-grade lymphomas eventually transform into more aggressive forms of lymphoma/leukemia.

People with intermediate or more aggressive forms of lymphoma usually present with accompanying constitutional symptoms such as fever, drenching night sweats, or weight loss. Frequently, there is increased susceptibility to bacterial, viral, and fungal infections associated with hypogammaglobulinemia and a poor humoral antibody response, rather than the impaired cellular immunity seen with HL. Because of their high growth fraction, these lymphomas tend to be sensitive to radiation and chemotherapy.

**Diagnosis and Treatment.** A lymph node biopsy is used to confirm the diagnosis of NHL and immunophenotyping to determine the lineage and clonality. Staging of the disease is important in selecting a treatment for people with NHL.

Treatment of NHL depends on the histologic type, stage of the disease, and clinical status of the person. For early-stage disease involving a single or limited node involvement, localized radiation may be used as a single treatment modality. However, because most people who present with indolent lymphoma have disseminated disease at the time of diagnosis, combination chemotherapy, biotherapy, and adjuvant radiation therapy are recommended.

**KEY POINTS**

**MALIGNANT LYMPHOMAS**

- The lymphomas represent malignancies that arise in the peripheral lymphoid tissues.
- NHLs represent a group of heterogeneous lymphocytic cancers that are multicentric in origin and spread to various tissues throughout the body, including the bone marrow.
- HL is a group of cancers characterized by Reed-Sternberg cells that begins as a malignancy in a single lymph node and then spreads to contiguous lymph nodes.
Hodgkin Lymphoma

Hodgkin lymphoma is a specialized form of lymphoma that features the presence of an abnormal cell called a Reed-Sternberg cell.4 Because of improved treatment methods, death rates have decreased by more than 60% since the early 1970s. Distribution of the disease is bimodal. It occurs more frequently in two separate age groups, the first in early adulthood (15 to 40 years) and the second in older adulthood (55 years of age or older).27 Only 10% to 15% of HL cases occur in children or adolescents.27

HL differs from NHL in several respects. First, it usually arises in a single node or chain of nodes, whereas NHL frequently originates at extranodal sites and spreads to anatomically contiguous nodes.4 Second, HL is characterized by the presence of large, atypical, mononuclear tumor cells, called Reed-Sternberg cells (Fig. 28.9). These cells, which frequently constitute less than 1% of the total cell population, are a diagnostic hallmark of the disease.

Etiology and Pathogenesis. As with NHLs, the cause of HL is largely unknown. Although exposure to carcinogens and viruses as well as genetic and immune mechanisms have been proposed as causes, none has been proved to be involved in the pathogenesis of the disease.

The origin of the neoplastic Reed-Sternberg cell of HL has been difficult to study, in large part because these cells do not express many of the markers found on lymphocytes. It is only recently that methods have been developed that allow for the microanalysis of these cells and their variants. These studies have shown that the Reed-Sternberg cells of most individual cases harbor identical immunoglobulin genes that show evidence of mutation, establishing the cell of origin as a germinal center or postgerminal center B cell.

Classification. The WHO classification proposed classifying HL into two major categories: nodular lymphocyte-predominant HL and classic HL. Nodular lymphocyte-predominant HL represents only a small portion of all cases of HL and is a unique form that generally exhibits a nodular growth pattern, with or without diffuse areas and with rare Reed-Sternberg cells called “popcorn” or “L&H” (lymphohistiocytic) cells. It is often localized rather than disseminated at the time of diagnosis, exhibits a slowly progressive course, and has an overall survival rate greater than 80%.4

Classic HL is characterized by clonal proliferation of typical mononuclear Hodgkin cells and multinucleated Reed-Sternberg cells with invariable expression of CD30. Four variants of classic HL have been described: nodular sclerosis, mixed cellularity, lymphocyte-rich, and lymphocyte-depleted. The nodular sclerotic type is the most common and is often found in adolescent and young adult women, 15 to 35 years of age.4 Lymphocyte-rich HL is a newly defined entity, and lymphocyte-depleted HL is rarely diagnosed.

Clinical Manifestations. Most people with HL present with painless enlargement of a single node or group of nodes. The initial lymph node involvement typically is above the level of the diaphragm (i.e., in the neck, supraclavicular area, or axilla). Mediastinal masses are frequent and are sometimes discovered on routine chest radiography. There may be complaints of chest discomfort with cough or dyspnea. Involvement of subdiaphragmatic lymph nodes at the time of presentation is unusual and more common in older men. Additional symptoms that suggest HL include fevers, chills, night sweats, and weight loss. Pruritus and intermittent fevers associated with night sweats are classic symptoms of HL.

Other symptoms such as fatigue and anemia are indicative of disease spread. In the advanced stages of HL, the liver, spleen, lungs, digestive tract, and, occasionally, the CNS may be involved (Fig. 28.10). As the disease progresses, the rapid proliferation of abnormal lymphocytes leads to an immunologic defect, particularly in cell-mediated responses, rendering the person more susceptible to viral, fungal, and protozoal infections. Anergy, or the failure to develop a positive response to skin tests such as the tuberculin test, is common early in the course of the disease.

Diagnosis and Treatment. A definitive diagnosis of HL requires that the Reed-Sternberg cell be present in a biopsy specimen of lymph node tissue. Multiple types of imaging including a bipedal lymphangiogram may detect structural changes in the lymph nodes too small to visualize on computed tomography (CT) scan. A bilateral bone marrow biopsy is usually performed on people who are suspected of having disseminated disease.

People with HL are staged according to the number of lymph nodes involved, whether the lymph nodes are on one or both sides of the diaphragm, and whether there is disseminated disease involving the bone marrow, liver, lung, or skin. The staging of HL is of great clinical importance because the choice of treatment and the prognosis ultimately are related to the distribution of the disease.

Irradiation and chemotherapy are used in treating the disease. Most people with localized disease are treated with radiation therapy. A combined approach using radiation, biotherapy, and chemotherapy is used in people with advanced disease. As the accuracy of staging techniques, delivery of radiation, and curative efficacy of combination chemotherapy regimens have improved, the survival of people with HL also has improved.

Leukemias

The leukemias are malignant neoplasms of cells originally derived from hematopoietic precursor cells. They are characterized by diffuse replacement of bone marrow with unregulated, proliferating, immature neoplastic cells. In most cases, the leukemic cells spill out into the blood, where they are seen in large numbers. The term leukemia (i.e., “white blood”) was first used by Virchow to describe a reversal of the usual ratio of red blood cells to white blood cells. The leukemic cells may also infiltrate the liver, spleen, lymph nodes, and other tissues throughout the body, causing enlargement of these organs.

Approximately 44,600 new cases of leukemia were diagnosed in the United States in 2011, and approximately 21,780 people died of the disease. Leukemia is the most common cause of cancer in children and adolescents. It accounts for about one of three cancers in children. Although it commonly is thought of as a childhood disease, leukemia is diagnosed 10 times more frequently in adults than children.

Classification

The leukemias commonly are classified according to their predominant cell type (i.e., lymphocytic or myelocytic) and whether the condition is acute or chronic. Biphenotypic leukemias demonstrate characteristics of both lymphoid and myeloid lineages. A rudimentary classification system, the French-American-British (FAB) Cooperative Group classification, is still being used and divides leukemia into four types: acute lymphocytic (lymphoblastic) leukemia (ALL), chronic lymphocytic leukemia (CLL), acute myelogenous (myeloblastic) leukemia (AML), and chronic myelogenous leukemia (CML). However, new classification systems with multiple subtypes that differentiate many characteristics and employ gene expression profiling are being used clinically for diagnosis and treatment. The lymphocytic leukemias involve immature lymphocytes and their progenitors that originate in the bone marrow but infiltrate the spleen, lymph nodes, CNS, and other tissues. The myelogenous leukemias involve the pluripotent myeloid stem cells in bone marrow and interfere with the maturation of all blood cells, including the granulocytes, erythrocytes, and thrombocytes.

Etiology and Molecular Biology

The causes of leukemia are largely unknown. The incidence of leukemia among people who have been exposed to high levels of radiation is unusually high. An increased incidence of leukemia also is associated with exposure to benzene, many unknown toxins, drugs, chemicals, and gases. Leukemia may occur as a second cancer after aggressive chemotherapy for other cancers, such as HL. The existence of a genetic predisposition to development of acute leukemia is suggested by the increased leukemia incidence among a number of congenital disorders, including Down syndrome, neurofibromatosis, and Fanconi anemia. There also are numerous reports of multiple cases of acute leukemia occurring within the same family.

The molecular biology of leukemia suggests that the event or events causing the disorders exert their effects through dysregulation of genes that normally regulate blood cell development and homeostasis. Cytogenetic studies have shown that recurrent chromosomal changes occur in over half of all cases of leukemia. Most commonly, these are structural changes classified as translocations, written t(8;21), in which a part of one (e.g., 8) chromosome becomes located on another chromosome (e.g., 21) and vice versa; inversions, written inv(16), in which part of a chromosome (e.g., 16) is upside down and now in reverse order, but still attached to the original chromosome; and deletions, written del(7) or −7, in which part of a chromosome (e.g., 7) has been lost. It is the disruption or dysregulation of specific genes and gene products occurring at the site of these chromosome aberrations that contributes to the development of leukemia. In many instances, these genes and their products have been shown to be directly or indirectly involved in the normal development or maintenance of the hematopoietic system. Thus, it would appear that leukemia results, at least in part, from disruption in the activity of genes that normally regulate blood cell development. Figure 28.11 compares a normal blood smear to one with leukemia. Advances in molecular biology regarding leukemia are beginning to provide a more complete understanding of the molecular complexity of leukemia for the purposes of diagnosis, classification, treatment, and monitoring of clinical outcomes.

One of the more studied translocations is the Philadelphia chromosome, which was the first chromosomal abnormality identified in cancer. The Philadelphia chromosome translocation, t(9;22), represents a reciprocal translocation between the long arm of chromosome 22 and the long arm of
During the translocation, a large portion of 22q is translocated to 9q, and a smaller piece of 9q is moved to 22q (Fig. 28.12). The portion of 9q that is translocated contains ABL, a proto-oncogene that is the cellular homolog of the Abelson murine leukemic virus. The ABL gene is received at a specific site on 22q called the breakpoint cluster region (BCR). The resulting BCR-ABL fusion gene codes for a novel protein that differs from that of the normal ABL gene in that it possesses tyrosine kinase activity (a characteristic activity of transforming genes). The presence of the tyrosine kinase generated by the fusion gene allows affected cells to bypass the regulated signals that control normal cell growth and differentiation and instead undergo malignant transformation to become leukemic cells. The Philadelphia chromosome translocation is found in more than 90% of people with CML and in some people with acute leukemia.

The development of tyrosine kinase inhibitors has contributed to the targeted approach for treatment of leukemias that display the Philadelphia chromosome translocation.

**Acute Leukemias**

The acute leukemias are cancers of the hematopoietic progenitor cells. They usually have a sudden onset with signs and symptoms related to depressed bone marrow function (Table 28.1). There are two types of acute leukemia: ALL and AML. ALL occurs most frequently in children, accounting for three out of four cases of childhood leukemia cases. However, about one third of cases of ALL occur in adults, and most of the deaths from the disease occur in adults (about four out of five). In the United States, over 6000 new cases of ALL in children and adults are predicted in 2012. In addition, over 1400 cases of ALL will result in death. AML is mainly a disease of older adults, but it is also seen in children and young adults. In children and adolescents, AML accounts for one in four cases of leukemia. The American Cancer Society predicts there will be 12,950 new cases of AML in 2011 with approximately 9050 deaths/year.
(i.e., more than 50 chromosomes), polyploidy (i.e., three or more sets of chromosomes), and chromosomal translocations and deletions. Many of these chromosomal aberrations serve to dysregulate the expression and function of transcription factors required for normal hematopoietic cell development.

The AMLs are a diverse group of neoplasms affecting myeloid precursor cells in the bone marrow. Most are associated with acquired genetic alterations that inhibit terminal myeloid differentiation. As a result, normal marrow elements are replaced by an accumulation of relatively undifferentiated blast cells with a resultant suppression of the remaining progenitor cells that leads to anemia, neutropenia, and thrombocytopenia. Specific chromosomal abnormalities, including translocations, are seen in a large number of AMLs. One subtype of AML, acute promyelocytic leukemia, which represents 10% of adult cases of AML, is associated with a t(15;17) chromosomal translocation. This translocation produces a fusion gene that encodes a portion of the transcription factor, retinoic acid receptor-a (RARa), fused to a portion of another protein, PML. This change in the retinoic acid receptor produces a block in differentiation that can be overcome with pharmacologic doses of retinoic acid.

Clinical Manifestations. Although ALL and AML are distinct disorders, they typically present with similar clinical features. Both are characterized by an abrupt onset of symptoms, including fatigue resulting from anemia; low-grade fever, night sweats, and weight loss due to the rapid proliferation and hypermetabolism of the leukemic cells; bleeding due to a decreased platelet count; and bone pain and tenderness due to bone marrow expansion. Infection results from neutropenia, with the risk of infection rising steeply as the neutrophil count falls below 500 cells/µL. Generalized lymphadenopathy, splenomegaly, and hepatomegaly caused by infiltration of leukemic cells occur in all acute leukemias but are more common in ALL.

In addition to the common manifestations of acute leukemia (i.e., fatigue, weight loss, fever, easy bruising), infiltration of malignant cells in the skin, gums, and other soft tissues is particularly common in the monocytic form of AML. The leukemic cells may also cross the blood–brain barrier and establish sanctuary in the CNS. CNS involvement is more common

*Manifestations vary with the type of leukemia.*
in ALL than AML, and is more common in children than adults. Signs and symptoms of CNS involvement include cranial nerve palsies, headache, nausea, vomiting, papilledema, and occasionally seizures and coma.

*Leukostasis* is a condition in which the circulating blast count is markedly elevated (usually 100,000 cells/µL). The high number of circulating leukemic blasts increases blood viscosity and predisposes to the development of leukostatic emboli with obstruction of small blood vessels in the pulmonary and cerebral circulations. Occlusion of the pulmonary vessels leads to vessel rupture and infiltration of lung tissue, resulting in sudden shortness of breath and progressive dyspnea. Cerebral leukostasis leads to diffuse headache and lethargy, which can progress to confusion and coma. Once identified, leukostasis requires immediate and effective treatment to lower the blast count rapidly. Initial treatment uses apheresis to remove excess blast cells, followed by chemotherapy to stop leukemic cell production in the bone marrow.32

*Hyperuricemia* occurs as the result of increased proliferation or increased breakdown of purine nucleotides (*i.e.*, one of the components of nucleic acids) secondary to the leukemic cell death that results from chemotherapy. It may increase before and during treatment. Prophylactic therapy with rasburicase (Elitek), a recombinant version of a urate oxidase enzyme, is generally administered to prevent renal complications secondary to uric acid crystallization in the urine filtrate.35,36

**Diagnosis.** A definitive diagnosis of acute leukemia is based on blood and bone marrow studies. It requires the demonstration of leukemic cells in the peripheral blood, bone marrow, or extramedullary tissue. Laboratory findings reveal the presence of immature white blood cells (blasts) in the circulation and bone marrow, where they may constitute 60% to 100% of the cells. As these cells proliferate and begin to crowd the bone marrow, the development of other blood cell lines in the marrow is suppressed. Consequently, there is a loss of mature myeloid cells, such as erythrocytes, granulocytes, and platelets. Anemia is almost always present, and the platelet count is decreased. Immunophenotyping is performed to determine the lineage subtype of the leukemia.32

Bone marrow biopsy may be used to determine the molecular characteristics of the leukemia, the degree of bone marrow involvement, and the morphology and histology of the disease. Cytogenetic studies, which are used to determine chromosomal abnormalities, are one of the most powerful prognostic indicators in acute leukemia. Certain chromosomal abnormalities respond more favorably to certain types of treatment and have a better prognosis than other abnormalities.

In ALL, the staging includes a lumbar puncture to assess CNS involvement. Imaging studies that include CT scans of the chest, abdomen, and pelvis may also be obtained to identify additional sites of disease.

**Treatment.** Treatment of ALL and AML consists of several phases and includes *induction therapy*, which is designed to elicit a remission; *intensification therapy*, which is used to produce a further reduction in leukemic cells after a remission is achieved; and *maintenance therapy*, which serves to maintain the remission. The goal of induction therapy is the production of a severe bone marrow response with destruction of leukemic progenitor cells followed by normal bone marrow recovery. The likelihood of achieving a remission depends on a number of factors, including age, type of leukemia, and stage of the disease at time of presentation. Of these factors, age is probably the most significant prognostic variable.

Massive necrosis of malignant cells can occur during the initial phase of chemotherapy treatment. This phenomenon, known as *tumor lysis syndrome*, can lead to life-threatening metabolic disorders, including hyperkalemia, hyperphosphatemia, hyperuricemia, hypomagnesemia, hypocalcemia, and acidosis, with the potential for causing acute renal failure. Aggressive prophylactic hydration with alkaline solutions and administration of rasburicase (Elitek) to reduce uric acid levels are used to counteract these effects.

As with ALL, treatment of AML consists of a number of phases. Treatment usually consists of induction therapy followed by intensive consolidation therapy. Induction therapy consists of intensive chemotherapy to effect aplasia of the bone marrow. During this period, supportive transfusion and treatment with antimicrobial agents are often needed.

Bone marrow or stem cell transplantation may be considered for people with ALL and AML who have failed to respond to other forms of therapy.32 Because of the risk of complications, bone marrow transplantation is not usually recommended for people older than 50 to 55 years of age.32

---

**KEY POINTS**

**LEUKEMIAS**

- Leukemias are malignant neoplasms arising from the transformation of a single blood cell line derived from hematopoietic stem cells.
- Because leukemic cells are immature and poorly differentiated, they proliferate rapidly and have a long life span, they do not function normally, they interfere with the maturation of normal blood cells, and they circulate in the bloodstream, cross the blood-brain barrier, and infiltrate many body organs.

**Chronic Leukemias**

In contrast to acute leukemias, chronic leukemias are malignancies involving proliferation of more fully differentiated myeloid and lymphoid cells. As with acute leukemia, there are two major types of chronic leukemia: CLL and CML. CLL accounted for approximately 14,570 new cases and 4380 deaths in the United States in 2011.37 It is mainly a disorder of older people. The average age at time of diagnosis is approximately 72 years. It is rarely seen in people younger...
than 40 years of age, and is extremely rare in children. CML accounted for about 5150 new diagnoses and 270 deaths in 2011 in the United States. As with CLL, it is predominantly a disorder of older adults, with an average age of approximately 67 years at time of diagnosis.

**Chronic Lymphocytic Leukemia.** CLL, a clonal malignancy of B lymphocytes, is the most common form of leukemia in adults in the Western world. In the past, CLL was viewed as a homogeneous disease of immature, immune-incompetent, minimally self-renewing B cells, which accumulated because of faulty apoptotic mechanisms. Some people with CLL survive for many years without therapy and eventually succumb to unrelated diseases, whereas others have a rapidly fatal disease despite aggressive therapy. Its heterogeneity is thought to reflect differences in immunoglobulin V-gene mutations, expression of cell surface CD markers (e.g., CD38), and presence of the zeta-associated protein (ZAP-70). ZAP-70 is an intracellular protein that promulgates activation signals delivered to T cells and NK cells by their surface receptors for antigens. It is rarely present in normal B cells but is found in people with CLL. People with leukemic cells having few or no V-gene mutations or with many CD38+ or ZAP-70+ B cells often have an aggressive course, whereas those with V-gene mutations but few CD38+ or ZAP-70+ B cells usually have a more indolent course.

The clinical signs and symptoms of CLL are largely related to the progressive infiltration of the bone marrow and lymphoid tissues by neoplastic lymphocytes and to secondary immunologic defects. People with the indolent form of CLL are often asymptomatic at the time of diagnosis, and lymphocytosis is noted on a complete blood count obtained for another, unrelated disorder. As the disease progresses, lymph nodes gradually increase in size and new nodes are involved, sometimes in unusual areas such as the scalp, orbit, pharynx, pleura, gastrointestinal tract, liver, prostate, and gonads. People with the aggressive form of CLL experience a more rapid sequence of clinical deterioration characterized by increasing lymphadenopathy, hepatosplenomegaly, fever, abdominal pain, weight loss, progressive anemia, and thrombocytopenia, with a rapid rise in lymphocyte count.

Hypogammaglobulinemia is common in CLL, especially in people with advanced disease. An increased susceptibility to infection reflects an inability to produce specific antibodies and abnormal activation of complement. The most common infectious organisms are those that require opsonization for bacterial killing, such as *Streptococcus pneumoniae*, *Staphylococcus aureus*, and *Haemophilus influenzae*.

The diagnostic hallmark of CLL is isolated lymphocytosis. The white blood cell count is usually greater than 20,000/µL and may be elevated to several hundred thousand. Usually, 75% to 98% are lymphocytes. The hematocrit and platelet counts are usually normal at presentation. Tests to determine the presence of mutated forms of the immunoglobulin gene (which currently can be detected only in research laboratories) and expression of the C38 surface antigen and the ZAP-70 protein may be used to determine whether the leukemia is the indolent or aggressive type. Cytogenetic studies may also provide prognostic information. The finding of deletion of chromosome 17p or 11q is a poor prognostic indicator.

Treatment of CLL usually depends on the presence of prognostic indicators. People with the low-risk or indolent form of CLL usually do not require specific treatment for many years after diagnosis and eventually die of apparently unrelated causes. Reassurance that people with the disorder can live a normal life for many years is important. Many people with intermediate-risk disease may remain stable for many years as well, whereas others may develop complications and need treatment within a few months. Most people with high-risk CLL require treatment at diagnosis. Complications such as autoimmune hemolytic anemia or thrombocytopenia may require treatment with corticosteroids or splenectomy.

In younger people with aggressive disease, an allogeneic ablative (destruction of bone marrow cells by irradiation or chemotherapy) or nonmyeloablative stem cell transplant is a treatment option. In a nonmyeloablative type of transplant, the goal is marrow suppression, destruction of leukemia cells by the donor’s lymphocytes, known as “graft-versus-leukemia” effect, and marrow recovery with donor cells.

**Chronic Myelogenous Leukemia.** CML is a disorder of the pluripotent hematopoietic progenitor cell. It is characterized by excessive proliferation of marrow granulocytes, erythroid precursors, and megakaryocytes. The CML cells harbor a distinctive cytogenic abnormality, the previously described *Philadelphia chromosome*. It is generally believed that CML develops when a single, pluripotent hematopoietic stem cell acquires a Philadelphia chromosome. Although CML originates in the pluripotent stem cells, granulocyte precursors remain the dominant leukemic cell type.

The clinical course of CML is commonly divided into three phases:

1. A chronic phase of variable length
2. A short accelerated phase
3. A terminal blast crisis phase

The onset of the chronic phase is usually slow, with nonspecific symptoms such as weakness and weight loss. The most characteristic laboratory finding at the time of presentation is leukocytosis with immature granulocyte cell types in the peripheral blood. Anemia and, eventually, thrombocytopenia develop. Anemia causes weakness, easy fatigability, and exertional dyspnea. Splenomegaly is often present at the time of diagnosis; hepatomegaly is less common; and lymphadenopathy is relatively uncommon.

The accelerated phase of CML is characterized by enlargement of the spleen and progressive symptoms. Splenomegaly often causes a feeling of abdominal fullness and discomfort. An increase in basophil count and more immature cells in the blood or bone marrow confirm transformation to the accelerated phase. During this phase, constitutional symptoms such as low-grade fever, night sweats, bone pain, and weight loss
develop because of rapid proliferation and hypermetabolism of the leukemic cells. Bleeding and easy bruising may arise from dysfunctional platelets. Generally, the accelerated phase is short (6 to 12 months).

The terminal blast crisis phase of CML represents evolution to acute leukemia and is characterized by an increasing number of myeloid precursors, especially blast cells, in the blood. Constitutional symptoms become more pronounced during this period, and splenomegaly may increase significantly. Isolated infiltrates of leukemic cells can involve the skin, lymph nodes, bones, and CNS. With very high blast counts (>100,000 cells/µL), symptoms of leukostasis may occur.

A diagnostic feature of CML is an elevated white blood count, with a median count of 150,000/µL at the time of diagnosis, although in some cases it is only modestly increased. The hallmark of the disease is the presence of the BCR-ABL gene product, which can be detected in the peripheral blood. This is best done using the polymerase chain reaction (PCR), which has supplanted cytogenetics in identifying the Philadelphia chromosome. Bone marrow examination is not usually necessary for diagnosis but is useful for prognosis and detecting additional chromosomal abnormalities.

The goals of treatment for CML include a hematologic response characterized by normalized blood counts; a cytogenetic response demonstrated by the reduction or elimination of the Philadelphia chromosome from the bone marrow; and a molecular response confirmed by the elimination of the BCR-ABL fusion protein. The only available curative treatment for CML is allogeneic bone marrow or stem cell transplantation. In most transplantation centers, full myeloablative transplants are available to children and adults younger than 60 years of age who have an HLA-matched sibling donor or an unrelated molecular-matched donor. Nonmyeloablative or “mini-transplants” are available to people younger than 70 years of age who have sibling HLA-matched or unrelated HLA-matched donors.

**Plasma Cell Dyscrasias**

Plasma cell dyscrasias are characterized by expansion of a single clone of immunoglobulin-producing plasma cells and a resultant increase in serum levels of a single monoclonal immunoglobulin or its fragments. The plasma cell dyscrasias include multiple myeloma; localized plasmacytoma (solitary myeloma); lymphoplasmacytic lymphoma; primary or immunocyte amyloidosis due to excessive production of light chains; and monoclonal gammopathy of undetermined significance (MGUS).

**Monoclonal gammopathy of undetermined significance** is characterized by the presence of the monoclonal immunoglobulin in the serum without other findings of multiple myeloma. MGUS is considered a premalignant condition. Approximately 2% per year of people with MGUS will go on to develop a plasma cell dyscrasia (multiple myeloma, lymphoplasmacytic lymphoma, or amyloidosis). The strong link between MGUS and multiple myeloma suggests that a first oncogenic event produces MGUS and a second event results in multiple myeloma.

**Multiple Myeloma**

Multiple myeloma is a B-cell malignancy of terminally differentiated plasma cells. Approximately 21,700 new diagnoses of multiple myeloma will be made in the United States in 2012 and about 10,710 people with multiple myeloma will die in 2012. It occurs most frequently in people older than 60 years of age, with the median age of people with multiple myeloma being 71 years.

The cause of multiple myeloma is unknown. Risk factors are thought to include chronic immune stimulation, autoimmune disorders, exposure to ionizing radiation, and occupational exposure to pesticides or herbicides (e.g., dioxin). Myeloma has been associated with exposure to Agent Orange during the Vietnam War. A number of viruses have been associated with the pathogenesis of myeloma.

**Pathogenesis.** Multiple myeloma is characterized by proliferation of malignant plasma cells in the bone marrow and osteolytic bone lesions throughout the skeletal system (Fig. 28.14). As with other hematopoietic malignancies, it is now recognized that multiple myeloma is associated with chromosomal abnormalities, including deletions of 13q and translocations involving the IgG locus on chromosome 14. One fusion partner is a fibroblast growth factor receptor gene on chromosome 4, which is truncated to produce a constitutively active receptor. Changes also occur in the bone marrow microenvironment, including the induction of angiogenesis, the suppression of cell-mediated immunity, and the development of paracrine signaling loops involving cytokines such as IL-6 and vascular endothelial growth factor. Other growth factors that are implicated in multiple myeloma include granulocyte CSF, interferon-α, and IL-10. The development of bone lesions in multiple myeloma is thought to be related to an
increase in expression by osteoblasts of the receptor activator of the nuclear factor-xB (NF-xB) ligand (RANKL).32

One of the characteristic features resulting from the proliferating osteoclasts in multiple myeloma is the unregulated production of a monoclonal antibody referred to as the M protein because it is detected as an M spike on protein electrophoresis. In most cases the M protein is either IgG (60%) or IgA (20% to 25%).41 In the remaining 15% to 20% of cases, plasma cells produce only abnormal proteins, termed Bence Jones proteins, that consist of light chains of the immunoglobulin molecule. Because of their low molecular weight, the Bence Jones proteins are readily excreted in the urine. People with this form of the disease (light-chain disease) have Bence Jones proteins in their serum, but lack the M component. However, up to 80% of myeloma cells produce both complete immunoglobulins as well as excess light chains. Therefore, both M proteins and Bence Jones proteins are present. Many of the light-chain proteins are directly toxic to renal tubular structures, which may lead to tubular destruction and, eventually, to renal failure.

**Clinical Manifestations.** The main sites involved in multiple myeloma are the bones and bone marrow. In addition to the abnormal proliferation of marrow plasma cells, there is proliferation and activation of osteoclasts, which leads to bone resorption and destruction (Fig. 28.15). This increased bone resorption predisposes the person to pathologic fractures and hypercalcemia. Paraproteins secreted by the plasma cells may cause a hyperviscosity of body fluids and may break down into amyloid, a proteinaceous substance deposited between cells, causing heart failure and nephropathy. Although multiple myeloma is characterized by excessive production of monoclonal immunoglobulin, levels of normal immunoglobulins are usually depressed. This contributes to a general susceptibility to recurrent bacterial infections.

The malignant plasma cells also can form plasmacytomas (plasma cell tumors) in bone and soft tissue sites. The most common site of soft tissue plasmacytomas is the gastrointestinal tract. The development of plasmacytomas in bone tissue is associated with bone destruction and localized pain. Osteolytic lesions and compression fractures may be seen in the axial skeleton and proximal long bones. Occasionally, the lesions may affect the spinal column, causing vertebral collapse and spinal cord compression.

Bone pain is one of the first symptoms to occur in approximately three fourths of all people diagnosed with multiple myeloma. Bone destruction also impairs the production of erythrocytes and leukocytes and predisposes the patient to anemia and recurrent infections. Many people experience weight loss and weakness. Renal insufficiency occurs in approximately half of all people with multiple myeloma. Neurologic manifestations caused by neuropathy or spinal cord compression also may be present.

**Diagnosis and Treatment.** Diagnosis of multiple myeloma is based on clinical manifestations, blood tests, and bone marrow examination.41 The classic triad of bone marrow plasmacytosis (more than 10% plasma cells), lytic bone lesions, and either the serum M-protein spike or the presence of Bence Jones proteins in the urine is definitive for a diagnosis of multiple myeloma. Bone radiographs are important in establishing the presence of bone lesions. Anemia is almost universal. Other laboratory features include hypercalcemia, an elevated erythrocyte sedimentation rate, and signs of kidney failure.

The treatment of multiple myeloma is changing rapidly.41,42 For several decades, melphalan (an alkylating agent) and prednisone have remained the cornerstone for treatment of multiple myeloma. Cumulative exposure to melphalan, however, is associated with increased risk of marrow toxicity, including myelodysplasia, acute leukemia, and impaired stem cell production. This is an important consideration in people who are candidates for autologous stem cell transplants. The addition of anthracyclines, alternative alkylating agents, and interferon has yielded minimal improvement in treatment outcomes. Although the incorporation of new classes of medications in the treatment of multiple myeloma has seen a shift in the older treatment regimens, the conventional approaches have not been excluded.

High-dose chemotherapy with autologous stem cell transplantation is considered appropriate front-line therapy.
for people younger than 70 years of age newly diagnosed with multiple myeloma. Allogeneic transplantation offers prolonged disease-free outcomes and potential cure, but at a high cost of treatment-related mortality. Because of this, “mini-transplants” using non–marrow-ablative chemotherapy may be used to provide sufficient immune suppression to allow donor engraftment and subsequent graft-versus-tumor effect.

IN SUMMARY

The lymphomas (NHL and HL) represent malignant neoplasms of cells native to lymphoid tissue that have their origin in the secondary lymphoid structures such as the lymph nodes and MALTs. The NHLs are a group of neoplastic disorders that originate in the lymphoid tissues, usually the lymph nodes. The NHLs are multicentric in origin and spread early to various lymphoid tissues throughout the body, especially the liver, spleen, and bone marrow. HL is characterized by painless and progressive enlargement of a single node or group of nodes. It is believed to originate in one area of the lymphatic system and, if unchecked, spreads throughout the lymphatic network.

The leukemias are malignant neoplasms of the hematopoietic precursor cells that originate in the bone marrow. They are classified according to cell type (i.e., lymphocytic or myelocytic) and whether the disease is acute or chronic. The lymphocytic leukemias involve immature lymphocytes and their progenitors that originate in the bone marrow but infiltrate the spleen, lymph nodes, CNS, and other tissues. The myelogenous leukemias involve the pluripotent myeloid stem cells in bone marrow and interfere with the maturation of all blood cells, including the granulocytes, erythrocytes, and thrombocytes.

The acute leukemias (i.e., ALL, which primarily affects children, and AML, which primarily affects adults) have a sudden onset with symptoms of depressed bone marrow function (anemia, fatigue, bleeding, and infections); bone pain; and generalized lymphadenopathy, splenomegaly, and hepatomegaly. The chronic leukemias, which largely affect adults, have a more insidious onset. CLL often has the most favorable clinical course, with many persons living long enough to die of other, unrelated causes. The course of CML is slow and progressive, with transformation to a course resembling that of AML.

Multiple myeloma is a plasma cell dyscrasia characterized by expansion of a single clone of immunoglobulin-producing plasma cells and a resultant increase in serum levels of a single monoclonal immunoglobulin or its fragments. The main sites involved in multiple myeloma are the bones and bone marrow. In addition to the abnormal proliferation of marrow plasma cells, there is proliferation and activation of osteoclasts that leads to bone resorption and destruction, and predisposes to increased risk for pathologic fractures and development of hypercalcemia. Paraproteins secreted by the plasma cells may cause hyperviscosity of body fluids and may break down into amyloid, a proteinaceous substance deposited between cells that can cause heart failure and neuropathy. Bone marrow involvement leads to increased risk of infection due to suppressed humoral and cell-mediated immunity and anemia due to impaired red cell production.

REVIEW EXERCISES

1. A mother brings her 4-year-old son into the pediatric clinic because of irritability, loss of appetite, w-grade fever, pallor, and complaints that his legs hurt. Blood tests reveal anemia, thrombocytopenia, and an elevated leukocyte count with atypical lymphocytes. A diagnosis of ALL is confirmed.

A. What is the origin of the anemia, thrombocytopenia, elevated leukocyte count, and atypical lymphocytes seen in this child?

B. Explain the cause of the child’s fever, pallor, increased bleeding, and bone pain.

C. The parents are informed that the preferred treatment for ALL consists of aggressive chemotherapy with the purpose of achieving a remission. Explain the rationale for using chemotherapy to treat leukemia.

D. The parents are told that the child will need intrathecal chemotherapy administered by a lumbar puncture. Why is this treatment necessary?

2. A 36-year-old man presents to his health care clinic with fever, night sweats, weight loss, and a feeling of fullness in his abdomen. Subsequent lymph node biopsy reveals a diagnosis of NHL.

A. Although lymphomas can originate in any of the lymphoid tissues of the body, most originate in the lymph nodes, and most (80% to 85%) are of B-cell origin. Hypothesize as to why B cells are more commonly affected than T cells.

B. Monoclonal antibodies are being used in the treatment of NHL. Explain how these agents exert its effect and why they are specific for B-cell lymphomas.

Mr. Brown, a 65-year-old male, presents with concerns about high blood pressure. He recently checked his blood pressure at a retail store, and the readout suggested that he consult a health care provider. Approximately 8 years ago he was prescribed an angiotensin-converting enzyme (ACE) inhibitor to lower his blood pressure, which was “borderline hypertensive.” At that time he refused a diuretic because he feared the side effect of frequent urination. He completed the 30-day prescription, thought that he was cured, and never refilled his prescription or followed up with his health care provider.

His father died at 70 of a “heart attack” and had been diagnosed with hypertension and an aortic abdominal aneurysm in his 50s. Mr. Brown quit smoking in his 20s and has an occasional glass of wine. He reports shortness of breath with exertion and denies chest pain. His vital signs are as follows: blood pressure, 160/90 mm Hg; pulse, 90/minute; respiration rate, 16/minute; temperature, 98.5°F; height, 5’8”; weight, 190 lb; and body mass index (BMI), 28.9 (classified as overweight). Physical examination reveals jugular vein distention (JVD); a loud, systolic ejection murmur without audible thrill (abbreviated as III/VI SEM); and mild bilateral edema in his lower limbs. An electrocardiogram (ECG) reveals multiple incidences of premature atrial contractions (PACs). The ECG shows left ventricular hypertrophy and atrial enlargement and an ejection fraction (EF) of 40%. His fasting lipoprotein profile is as follows: total cholesterol, 260; LDL cholesterol, 150; HDL cholesterol, 35; and triglycerides, 150 (all in mg/dL). Mr. Brown is diagnosed with hypertension, hypercholesteremia, and heart failure. According to the New York Heart Association system of classification, his heart failure is categorized as class II (NYHA II), meaning that his symptoms are mild. He is prescribed a statin, a beta-adrenergic receptor blocker, a diuretic, and an ACE inhibitor and scheduled to have a cardiac catheterization. Mr. Brown is also educated about the importance of follow-up care and provided with a low-sodium, low-cholesterol diet plan and an exercise regimen (for after his cardiac catheterization). The pathophysiology of Mr. Brown’s hypertension, hypercholesteremia, and heart failure is discussed in Chapters 29 to 34.
Structure and Function of the Cardiovascular System

The Lymphatic System

NEURAL CONTROL OF CIRCULATORY FUNCTION
- Autonomic Nervous System Regulation
- Autonomic Regulation of Cardiac Function
- Autonomic Regulation of Vascular Function
- Autonomic Neurotransmitters
- Central Nervous System Responses

The main function of the circulatory system, which consists of the heart and blood vessels, is transportation. The circulatory system delivers oxygen and nutrients needed for metabolic processes to the tissues. It carries waste products from the tissues to the kidneys and other excretory organs for elimination. It also circulates electrolytes and hormones needed to regulate body function. The circulatory system also plays an important role in body temperature regulation by transporting core heat to the periphery, where it is dissipated into the external environment.

ORGANIZATION OF THE CIRCULATORY SYSTEM

After completing this section of the chapter, you should be able to meet the following objectives:

- Compare the function and distribution of blood flow and blood pressure in the systemic and pulmonary circulations.
- State the relation between blood volume and blood pressure in arteries, veins, and capillaries of the circulatory system.
Pulmonary and Systemic Circulations

The circulatory system can be divided into two parts:

- The pulmonary circulation, which moves blood through the lungs and creates a link with the gas-exchange function of the respiratory system.
- The systemic circulation, which supplies all the other tissues of the body (Fig. 29.1).

The pulmonary circulation consists of the right heart, the pulmonary artery, the pulmonary capillaries, and the pulmonary veins. The large pulmonary vessels are unique in that the pulmonary artery is the only artery that carries venous blood and the pulmonary veins are the only veins that carry arterial blood. Pulmonary circulation is considered low pressure and low resistance since it is a short system only involving blood to and from the lungs. The low pressure of the pulmonary circulation allows blood to move through the lungs more slowly, which is important for gas exchange. The systemic circulation consists of the left heart, the aorta and its branches, the capillaries that supply the brain and peripheral tissues, and the systemic venous system and the vena cava. The veins from the lower portion of the body merge to form the inferior vena cava, and those from the head and upper extremities merge to form the superior vena cava, both of which empty into the right heart. This circulation is more complex with higher pressures since it involves a complex vascular tree that provides substantial resistance to blood flow due to the effects of gravity.

The heart, which propels blood through the circulatory system, consists of two pumps. The right heart propels blood through the gas-exchange vessels in the lungs, and the left heart propels blood through the vessels that supply all the other tissues in the body. Both sides of the heart are further divided into two chambers—an atrium and a ventricle. The atria function as reservoirs for blood returning to the heart from the body and lungs and as auxiliary pumps that assist in filling the ventricles. The ventricles are the main pumping chambers of the heart. The right ventricle pumps blood through the pulmonary artery to the lungs, and the left ventricle pumps blood through the aorta into the systemic circulation. The ventricular chambers of the right and left heart have unidirectional inlet valves and outlet valves that act reciprocally (i.e., one set of valves is open while the other is closed) to control the direction of blood flow through the cardiac chambers.

Because it is a closed system, the effective function of the circulatory system requires that the outputs of both sides of the heart must pump the same amount of blood over time. If the output of the left heart were to fall below that of the right heart, blood would accumulate in the pulmonary circulation. Likewise, if the right heart were to pump less effectively than the left heart, blood would accumulate in the systemic circulation. However, the left and right heart seldom ejects exactly the same amount of blood with each beat. This is because blood return to the heart is affected by activities of daily living such as taking a deep breath or moving from the seated to standing position. These beat-by-beat variations in cardiac output are accommodated by the large storage capabilities of the venous system that allow for temporary changes in blood volume. The accumulation of blood occurs only when the storage capacity of the venous system has been exceeded.

**KEY POINTS**

**FUNCTIONAL ORGANIZATION OF THE CIRCULATORY SYSTEM**

- The circulatory system consists of the heart, which pumps blood; the arterial system, which distributes oxygenated blood to the tissues; the venous system, which collects deoxygenated blood from the tissues and returns it to the heart; and the capillaries, where exchange of gases, nutrients, and wastes takes place.
- The circulatory is a closed system that is divided into two parts: the low-pressure pulmonary circulation, linking circulation and gas exchange in the lungs, and the high-pressure systemic circulation, providing oxygen and nutrients to the tissues.
Volume and Pressure Distribution

Blood flow in the circulatory system depends on a blood volume that is sufficient to fill the blood vessels and a pressure difference across the system that provides the force to move blood forward. The total blood volume is a function of age and body weight, ranging from 85 to 90 mL/kg in the neonate and from 70 to 75 mL/kg in the adult. As shown in Figure 29.2, approximately 4% of the blood at any given time is in the left heart, 16% is in the arteries and arterioles, 4% is in the capillaries, 64% is in the venules and veins, and 4% is in the right heart. The arteries and arterioles, which have thick, elastic walls and function as a distribution system to carry blood away from the heart, have the highest pressure. Arterioles provide the bulk of resistance to the circulatory flow and are thus called resistance vessels. They are able to resist since smooth muscle fibers wrap around their walls. The capillaries are small, thin-walled vessels that link the arterial and venous sides of the circulation and allow the exchange of oxygen and metabolites generated by the various tissues. Because of their small size and large surface area, the capillaries contain the smallest amount of blood. The venules and veins, which contain the largest amount of blood, are thin-walled, high compliance vessels that function as a reservoir to collect blood from the capillaries and return it to the right heart.

Blood moves from the arterial to the venous side of the circulation along a pressure gradient, moving from an area of higher pressure to one of lower pressure. The pressure distribution in the different parts of the circulation is almost an inverse of the volume distribution (see Fig. 29.2). Thus, the pressure in the arterial side of the systemic circulation, which contains only approximately one sixth of the blood volume, is much greater than the pressure on the venous side of the circulation, which contains approximately two thirds of the blood. This pressure and volume distribution is due in large part to the structure and relative elasticity of the arteries and veins.

It is the pressure difference between the arterial and venous sides of the circulation (approximately 84 mm Hg) that provides the driving force for flow of blood in the systemic circulation. The pulmonary circulation has a similar arterial–venous pressure difference, but of a lesser magnitude. Because the pulmonary and systemic circulations are connected and function as a closed system, blood can be shifted from one circulation to the other. In the pulmonary circulation, the blood volume, which approximates 4.7 to 5 L in the average-size adult, can vary from as low as 50% of normal to as high as 200% of normal. An increase in intrathoracic pressure, which impedes venous return to the right heart, can produce a transient shift from the pulmonary to the systemic circulation of as much as 250 mL of blood. Body position also affects the distribution of blood volume. In the recumbent position, approximately 25% to 30% of the total blood volume is in the central circulation. On standing, this blood is displaced to the lower part of the body due to the forces of gravity. A shift of blood from one system to the other has a much greater effect in the pulmonary circulation since it contains less blood volume than the systemic circulation.

The circulatory system functions as a transport system that circulates nutrients and other materials to the tissues and removes waste products. The circulatory system can be divided into two parts—the pulmonary circulation and the systemic circulation. The heart pumps blood throughout the system, and the blood vessels serve as tubes through which blood flows. The arterial system carries blood from the heart to the tissues and the veins carry it back to the heart. The cardiovascular system is a closed system with a right and left heart connected in series. The systemic circulation (which involves the left heart) provides blood...
flow for all the tissues. The right heart provides blood flow for the pulmonary circulation. Blood moves throughout the circulation along a pressure gradient, moving from the high-pressure arterial system to the low-pressure venous system. In the circulatory system, pressure is inversely related to volume. The pressure on the arterial side of the circulation, which contains only approximately one sixth of the blood volume, is much greater than the pressure on the venous side of the circulation, which contains approximately two thirds of the blood.

**PRINCIPLES OF BLOOD FLOW**

After completing this section of the chapter, you should be able to meet the following objectives:

- Define the term *hemodynamics* and describe the effects of blood pressure, vessel radius, vessel length, vessel cross-sectional area, and blood viscosity on blood flow.
- Use the law of Laplace to explain the effect of radius size on the pressure and wall tension in a vessel.
- Use the term *compliance* to describe the characteristics of arterial and venous blood vessels.

The term *hemodynamics* refers to the principles that govern blood flow in the circulatory system. These basic principles of physics, specifically called Ohm law, are the same as those applied to the movement of fluid in general. The concepts of flow, pressure, resistance, and capacitance as applied to blood flow in the cardiovascular system will be used in subsequent chapters to describe the hemodynamic changes that occur with disorders of the cardiovascular system.

**Relationships between Blood Flow, Pressure, and Resistance**

The most important factors governing the flow of blood in the cardiovascular system are pressure, resistance, and flow. Ohm law states that current (I) equals the voltage difference (ΔV) divided by the resistance (R). When relating this to blood flow, the voltage difference is the pressure difference or pressure gradient (ΔP), the resistance is the resistance to flow (R), and the current is the blood flow (F).\(^1\) Blood flow (F) through a vessel or series of blood vessels is determined by the pressure difference (P₁ − P₂) between the two ends of the vessel and the resistance (R) that blood must overcome as it moves through the vessel (F = ΔP/R). In the cardiovascular system, blood flow is represented by the cardiac output. Resistance is the opposition to flow caused by friction between the moving blood and the stationary vessel wall. In the peripheral circulation, the collective resistance of all the vessels in that part of the circulation is referred to as the *peripheral vascular resistance* (PVR) or, sometimes, as the *systemic vascular resistance*. The flow, pressure, and resistance relationships also can be applied on a smaller scale to determine the blood flow and resistance to flow of a single organ such as the kidney. Renal artery pressure, renal vein pressure, and renal vascular resistance determine blood flow to the kidney.

**Resistance to Flow**

The blood vessels and the blood itself constitute resistance to flow. The French physician Poiseuille derived a helpful equation for understanding the relationship between resistance, blood vessel diameter (radius), and blood viscosity factors that affect blood flow. The equation \( F = \Delta P/R \times \pi \times r \) (radius)\(^4\) × L (length) × η (viscosity) expands on the previous equation, \( F = \Delta P/R \), by relating flow to several determinants of resistance—vessel radius and blood viscosity. The length of vessels does not usually change and 8 is a constant that does not change. Because flow is directly related to the fourth power of the radius, small changes in vessel radius can produce large changes in flow to an organ or tissue. For example, if the pressure remains constant, the rate of flow is 16 times greater in a vessel with a radius of 2 mm \((2 \times 2 \times 2 \times 2)\) than in a vessel with a radius of 1 mm. The total resistance offered by a set of blood vessels also depends on whether the vessels are arranged in series, in which blood flows sequentially from one vessel to another, or arranged in parallel, in which the total blood flow is distributed simultaneously among parallel vessels. The parallel arrangement allows each tissue to regulate its own blood flow so that the resistance is low.

Viscosity is the resistance to flow caused by the friction of molecules in a fluid. The viscosity of a fluid is largely related to its thickness. The more particles that are present in a solution, the greater the frictional forces that develop between the molecules. Unlike water, blood is a nonhomogeneous liquid that contains blood cells, platelets, fat globules, and plasma proteins that increase its viscosity. The red blood cells, which constitute 40% to 45% of the formed elements of the blood, largely determine the viscosity of the blood. A hematocrit measurement is performed in order to measure the proportion of red blood cells in blood. For example, if a person has a hematocrit of 38, then 38% of the blood volume is red blood cells. If the hematocrit increases, the viscosity increases and vice versa. Also, under special conditions, temperature may affect viscosity. There is a 2% rise in viscosity for each 1°C decrease in body temperature. This fact helps explain the sluggish blood flow seen in people with hypothermia.

**Velocity and Cross-Sectional Area**

*Velocity* is a distance measurement. It refers to the rate of displacement of a particle of fluid with respect to time (centimeters per second). *Flow* is a volume measurement. It refers to the displacement of a volume of fluid with respect to time (milliliter/second). The cross-sectional area of a vessel and the velocity of flow determine it. The same volume of blood flow must pass through each segment of the circulatory system each minute, allowing for continuous flow; the velocity is inversely
The term hemodynamics is used to describe factors such as (1) pressure and resistance, (2) vessel radius, (3) cross-sectional area and velocity of flow, and (4) laminar versus turbulent flow that affect blood flow through the blood vessels in the body.

**Pressure, Resistance, and Flow**

The flow \((F)\) of fluid through a tube, such as blood through a blood vessel, is directly related to a pressure difference \((P_1 - P_2)\) between the two ends of the tube and inversely proportional to the resistance \((R)\) that the fluid encounters as it moves through the tube.

The resistance to flow, in peripheral resistance units (PRUs), is determined by the blood viscosity, vessel radius, and whether the vessels are aligned in series or in parallel. In vessels aligned in series, blood travels sequentially from one vessel to another such that the resistance becomes additive (e.g., \(2 + 2 + 2 = 6\) PRU). In vessels aligned in parallel, such as capillaries, the blood is not confined to a single channel but can travel through each of several parallel channels such that the resistance becomes the reciprocal of the total resistance (i.e., \(1/R\)). As a result, there is no loss of pressure, and the total resistance (e.g., \(1/2 + 1/2 + 1/2 = 3/2\) PRU) is less than the resistance of any of the channels (i.e., 2) taken separately.

**Vessel Radius**

In addition to pressure and resistance, the rate of blood flow through a vessel is affected by the fourth power of its radius (the radius multiplied by itself four times). Thus, blood flow in vessel B with a radius of 2 mm will be 16 times greater than in vessel A with a radius of 1 mm.
### Cross-Sectional Area and Velocity of Flow

The velocity or rate of forward movement of the blood is affected by the cross-sectional area of a blood vessel. As the cross-sectional area of a vessel increases (sections 1 and 3), blood must flow laterally as well as forward to fill the increased area. As a result, the mean forward velocity decreases. In contrast, when the cross-sectional area is decreased (section 2), the lateral flow decreases and the mean forward velocity is increased.

### Laminar and Turbulent Flow

Blood flow is normally laminar, with platelets and blood cells remaining in the center or axis of the bloodstream. Laminar blood flow can be described as layered flow in which a thin layer of plasma adheres to the vessel wall, while the inner layers of blood cells and platelets shear against this motionless layer. This allows each layer to move at a slightly faster velocity, with the greatest velocity occurring in the central part of the bloodstream.

Turbulent blood flow is flow in which the blood elements do not remain confined to a definite lamina or layer, but develop vortices (i.e., a whirlpool effect) that push blood cells and platelets against the wall of the vessel. More pressure is required to force a given flow of blood through the same vessel (or heart valve) when the flow is turbulent rather than laminar. Turbulence can result from an increase in velocity of flow, a decrease in vessel diameter, or low blood viscosity. Turbulence is usually accompanied by vibrations of the fluid and surrounding structures. Some of these vibrations in the cardiovascular system are in the audible frequency range and may be detected as murmurs or bruits.

Proportional to the cross-sectional area of the vessel \( (v = F/A) \). For example, the smaller the cross-sectional area, the greater the velocity of flow. This phenomenon can be compared with cars moving from a two-lane to a single-lane section of a highway. To keep traffic moving at its original pace, cars would have to double their speed in the single-lane section of the highway. So it is with blood flow in the circulatory system.

The linear velocity of blood flow in the circulatory system varies widely from 30 to 35 cm/second in the aorta to 0.2 to 0.3 mm/second in the capillaries. This is because even though each individual capillary is very small, the total cross-sectional area of all the systemic capillaries greatly exceeds the cross-sectional area of other parts of the circulation. As a result of this large surface area, the slower movement of blood allows ample time for exchange of nutrients, gases, and metabolites between the tissues and the blood.

### Laminar versus Turbulent Flow

Ideally, blood flow is laminar or streamlined. This means that the blood components are arranged in layers so that the plasma is adjacent to the smooth, slippery endothelial surface of the blood vessel, and the blood elements, including the platelets, are in the center or axis of the bloodstream. This is also called the parabolic velocity profile of laminar flow. The molecules that touch the side of the vessel wall move slower because of adherence to the wall. This arrangement reduces friction by allowing the blood layers to slide smoothly over one another. The middle layers move more quickly, having the most rapid rate of flow.

Under certain conditions, blood flow switches from laminar to turbulent (or disorderly) flow. In turbulent flow, the laminar stream is disrupted, and the fluid particles become mixed radially (crosswise) and axially (lengthwise). Because energy is wasted in propelling blood both radially and axially, more
energy (pressure) is required to drive turbulent flow than laminar flow. Turbulent flow can be caused by a number of factors, including high velocity of flow, change in vessel diameter, an obstruction in a vessel, and low blood viscosity. The tendency for turbulence to occur is increased in direct proportion to the velocity of flow. Low blood viscosity allows the blood to move faster and accounts for the transient occurrence of heart murmurs in some people who are severely anemic (i.e., decreased hematocrit). Vibrations of the blood and surrounding structures often accompany turbulence. Some of these vibrations are in the audible range and can be heard using a stethoscope. For example, a heart murmur results from turbulent flow through a diseased heart valve that may be too narrow, too stiff, or too floppy. This turbulent flow causes a vibration called a murmur.

Wall Tension, Radius, and Pressure

In a blood vessel, wall tension is the force in the vessel wall that opposes the distending pressure inside the vessel. The French astronomer and mathematician Pierre de Laplace described the relationship between wall tension, pressure, and the radius of a vessel or sphere. This relationship, which has come to be known as the law of Laplace, can be expressed by the equation 

\[ P = \frac{T}{r} \]

where \( P \) is the intraluminal pressure, and \( r \) is vessel radius. Accordingly, the internal pressure expands the vessel until it is exactly balanced by the tension in the vessel wall. The smaller the radius, the greater the pressure needed to balance the wall tension. The law of Laplace can also be used to express the effect of the radius on wall tension \( (T = P \times r) \). This correlation can be compared with a partially inflated balloon. Because the pressure in the balloon is equal throughout, the tension in the section with the smaller radius is less than the tension in the section with the larger radius. The same principle holds true for an arterial aneurysm, in which the tension and risk of rupture increase as the aneurysm grows.

The law of Laplace was later expanded to include wall thickness \( (T = P \times \frac{r}{wall \ thickness}) \). Thus, wall tension is inversely related to wall thickness—the thicker the vessel wall, the lower the tension, and vice versa. In hypertension, arterial vessel walls hypertrophy and become thicker, thereby reducing the tension and minimizing wall stress.

Providing that the thickness of a vessel wall remains constant, it takes more pressure to overcome wall tension and keep a vessel open as its radius decreases in size. The critical closing pressure refers to the point at which blood vessels collapse so that blood can no longer flow through them. For example, in circulatory shock there is a decrease in blood volume and vessel radii, along with a drop in blood pressure. As a result, many of the small blood vessels collapse as blood pressure drops to the point where it can no longer overcome the wall tension. The collapse of peripheral veins often makes it difficult to insert venous lines that are needed for fluid and blood replacement.

Distention and Compliance

Compliance refers to the total quantity of blood that can be stored in a given portion of the circulation for each millimeter of mercury (mm Hg) rise in pressure. Compliance is the increase in volume divided by the increase in pressure. In other words, the ability of a vessel to distend and increase volume with increasing pressure is quantified as compliance. The most distensible of all vessels are the veins, which can increase their volume with only slight changes in pressure. This allows the veins to function as a reservoir for storing large quantities of blood that can be returned to the circulation when it is needed. The compliance of a vein is approximately 24 times that of its corresponding artery because it is 8 times as distensible and has a volume 3 times as great.

Blood flow is influenced by the pressure difference between the two ends of the vessel, the vessel length, its radius and cross-sectional area, the viscosity of the blood, and tension of the vessel wall. The rate of flow is directly related to the pressure difference between the two ends of the vessel and the vessel radius and inversely related to vessel length and blood viscosity. The cross-sectional area of a vessel influences the velocity of flow. As the cross-sectional area decreases, the velocity is increased, and vice versa. Laminar blood flow is a flow in which there is layering of blood components in the center of the bloodstream, which reduces friction. In contrast to laminar flow, turbulent flow is disordered flow, in which the blood moves crosswise and lengthwise in blood vessels. The law of Laplace describes the relationship between wall tension, transmural pressure, and radius. This law states that the pressure needed to overcome wall tension becomes greater as the radius decreases. Wall thickness also affects wall tension. It increases as the wall becomes thinner and decreases as the wall becomes thicker. Compliance of blood vessels refers to the total quantity of blood that can be stored in a given part of the circulatory system for each mm Hg rise in pressure.

IN SUMMARY

Blood flow is influenced by the pressure difference between the two ends of the vessel, the vessel length, its radius and cross-sectional area, the viscosity of the blood, and tension of the vessel wall. The rate of flow is directly related to the pressure difference between the two ends of the vessel and the vessel radius and inversely related to vessel length and blood viscosity. The cross-sectional area of a vessel influences the velocity of flow. As the cross-sectional area decreases, the velocity is increased, and vice versa. Laminar blood flow is a flow in which there is layering of blood components in the center of the bloodstream, which reduces friction. In contrast to laminar flow, turbulent flow is disordered flow, in which the blood moves crosswise and lengthwise in blood vessels. The law of Laplace describes the relationship between wall tension, transmural pressure, and radius. This law states that the pressure needed to overcome wall tension becomes greater as the radius decreases. Wall thickness also affects wall tension. It increases as the wall becomes thinner and decreases as the wall becomes thicker. Compliance of blood vessels refers to the total quantity of blood that can be stored in a given part of the circulatory system for each mm Hg rise in pressure.
THE HEART AS A PUMP

After completing this section of the chapter, you should be able to meet the following objectives:

- Describe the structural components and function of the pericardium, myocardium, endocardium, and the heart valves and fibrous skeleton.
- Define the terms preload and afterload.
- State the formula for calculating the cardiac output and explain the effects that venous return, cardiac contractility, and heart rate have on cardiac output.

The heart is a four-chambered muscular pump approximately the size of a man’s fist. It beats an average of 70 times each minute, 24 hours each day, 365 days each year for a lifetime. In 1 day, this pump moves more than 1800 gallons of blood throughout the body.

Functional Anatomy of the Heart

The heart is located between the lungs in the mediastinal space of the intrathoracic cavity in a loose-fitting sac called the pericardium. It is suspended by the great vessels, with its broader side (i.e., base) facing upward and its tip (i.e., apex) pointing downward, forward, and to the left. The heart is positioned obliquely, so that the right side of the heart is almost fully in front of the left side of the heart, with only a small portion of the lateral left ventricle on the frontal plane of the heart (Fig. 29.3). When the hand is placed on the thorax, the main impact of the heart’s contraction is felt against the chest wall at a point between the fifth and sixth ribs, a little below the nipple and approximately 3 inches to the left of the midline. This is called the point of maximum impulse (PMI).

The wall of the heart is composed of an outer epicardium, which lines the pericardial cavity; the myocardium or muscle layer; and the smooth endocardium, which lines the chambers of the heart (Fig. 29.4). A fibrous skeleton supports the valvular structures of the heart. The interatrial and interventricular septa divide the heart into a right and a left pump, each composed of two muscular chambers, including a thin-walled atrium, which serves as a reservoir for blood coming into the heart, and a thick-walled ventricle, which pumps blood out of the heart. The increased thickness of the left ventricular wall results from the additional work this ventricle is required to perform in order to move oxygenated blood out of the heart to the rest of his body, a common finding in hypertensive patients.

Pericardium

The pericardium forms a fibrous covering around the heart, holding it in a fixed position in the thorax and providing physical protection and a barrier to infection. The pericardium is a tri-layer sac consisting of a tough, outer fibrous layer and a thin, inner serous layer. The outer fibrous layer is attached to the great vessels that enter and leave the heart, the sternum, and the diaphragm. The fibrous pericardium is highly resistant to distention. It prevents acute dilation of the heart chambers and exerts a restraining effect on the left ventricle. The inner serous layer consists of a visceral layer and a parietal layer. The visceral layer, also known as the epicardium, covers the entire heart and great vessels and then folds over to form the parietal layer that lines the fibrous pericardium (see Fig. 29.4). Between the visceral and parietal layers is the pericardial cavity, a potential space that contains 30 to 50 mL of serous fluid. This fluid acts as a lubricant to minimize friction as the heart contracts and relaxes against surrounding structures.

Myocardium

The myocardium, or muscular portion of the heart, forms the wall of the atria and ventricles. Cardiac muscle cells, like skeletal muscle, are striated and composed of sarcomeres that contain actin and myosin filaments. They are smaller and more compact than skeletal muscle cells and contain many large mitochondria, reflecting their continuous energy needs.

The contractile properties of cardiac muscle are similar to those of skeletal muscle, except the contractions are involuntary and the duration of contraction is much longer. Unlike the orderly longitudinal arrangement of skeletal muscle fibers, cardiac muscle cells are arranged as an interconnecting lattice-work, with their fibers dividing, recombining, and then dividing again (Fig. 29.5A). Dense structures, called intercalated disks, separate the cardiac muscle fibers from neighboring cardiac muscle cells. The intercalated disks, which are unique to cardiac muscle, contain gap junctions that serve as low-resistance pathways for passage of ions and electrical impulses from one cardiac cell to another (see Fig. 29.5B). Thus, the myocardium behaves as a single unit, or syncytium, rather than as a group of isolated units, as does skeletal muscle. When one myocardial cell becomes excited, the impulse travels rapidly so the heart can beat as a unit. The heart muscle has two syncytiums—atrial and ventricular. The atrial syncytium constitutes the walls of the atria, and ventricular syncytium constitutes the walls of the ventricles. These two types of syncytiums allow the atria to contract prior to the ventricles, which is important to the heart pumping.

As in skeletal muscle, cardiac muscle contraction involves actin and myosin filaments, which interact and slide
UNIT VIII Disorders of Cardiovascular Function

Muscle relies more heavily than skeletal muscle on an influx of extracellular calcium ions for contraction. The cardiac glycosides (e.g., digoxin) are inotropic drugs that increase cardiac contractility by increasing the free calcium concentration in the vicinity of the actin and myosin filaments.

Endocardium

The endocardium is a thin, three-layered membrane that lines the heart. The innermost layer consists of smooth endothelial cells supported by a thin layer of connective tissue. The endothelial lining of the endocardium is continuous with the lining along one another during muscle contraction. A number of important proteins regulate actin–myosin binding. These include tropomyosin and the troponin complex. The troponin complex consists of three subunits (troponin T, troponin I, and troponin C) that regulate calcium-mediated contraction in striated muscle. In clinical practice, the measurement of serum levels of the cardiac forms of troponin T and troponin I is used in the diagnosis of myocardial infarction.

Although cardiac muscle cells require calcium for contraction, they have a less well-defined sarcoplasmic reticulum for storing calcium than skeletal muscle cells. Thus, cardiac muscle relies more heavily than skeletal muscle on an influx of extracellular calcium ions for contraction. The cardiac glycosides (e.g., digoxin) are inotropic drugs that increase cardiac contractility by increasing the free calcium concentration in the vicinity of the actin and myosin filaments.

**FIGURE 29.3** • (A) Anterior view of the heart, lungs, and great vessels (note that the lungs, which normally fold over part of the heart's anterior, have been pulled back). (B) The heart in relation to the sternum, ribs, and lungs. (C) Cross-section of the heart showing the increased thickness of the left ventricle compared with the right.
Heart Valves and Fibrous Skeleton

An important structural feature of the heart is its fibrous skeleton, which consists of four interconnecting valve rings and surrounding connective tissue. It separates the atria and ventricles and forms a rigid support for attachment of the valves and insertion of the cardiac muscle (Fig. 29.6). The tops of the valve rings are attached to the muscle tissue of the atria, pulmonary trunks, and aorta. The bottoms are attached to the ventricular walls. For the heart to function effectively, blood flow must occur in a one-way direction, moving in a forward (antegrade) manner through the chambers of the right heart to the lungs and then through the chambers of the left heart to the systemic circulation (Fig. 29.7). The heart’s two atrioventricular (AV) (i.e., tricuspid and mitral) valves and two semilunar (i.e., pulmonary and aortic) valves provide this unidirectional flow.

When closed, the AV valves prevent backflow of blood from the ventricles to the atria during systole. The thin edges of the AV valves form cusps, two on the left side of the heart (i.e., bicuspid valve) and three on the right side (i.e., tricuspid valve). The bicuspid valve is also known as the mitral valve. The AV valves are supported by the papillary muscles, which project from the wall of the ventricles, and the chordae tendineae,
which attach to the valve (Fig. 29.8). Contraction of the papillary muscles at the onset of systole ensures closure by producing tension on the leaflets of the AV valves before the full force of ventricular contraction pushes against them. The chordae tendineae are cordlike structures that support the AV valves and prevent them from everting into the atria during systole.

The aortic and pulmonic valves prevent backflow from the aorta and the pulmonary arteries into the ventricles during diastole. The pulmonic valve, which is located between the right ventricle and the pulmonary artery, controls the flow of blood into the pulmonary circulation, and the aortic valve, located between the left ventricle and the aorta, controls the flow of blood into the systemic circulation. Because their flaps are shaped like half-moons, they are often referred to as the semilunar valves. The semilunar valves have three cuplike cusps that are attached to the valve rings (Fig. 29.9B). These cuplike structures collect the retrograde, or backward, flow of blood that occurs toward the end of systole, enhancing closure. For the development of a perfect seal along the free edges of the semilunar valves, each valve cusp must have a triangular shape, which is facilitated by a nodular thickening at the apex of each leaflet (see Fig. 29.9A). Behind the semilunar valves are the sinuses of Valsalva. In these sinuses, eddy currents develop that tend to keep the valve cusps away from the vessel walls. The openings for the coronary arteries are located behind the right and left cusps, respectively, of the aortic valve. Were it not for the presence of the sinuses of Valsalva and the eddy currents, the valve cusps would block the coronary artery openings.
Simultaneous changes occur in left atrial pressure, left ventricular pressure, aortic pressure, ventricular volume, the ECG, and heart sounds during the cardiac cycle (Fig. 29.10).

The electrical activity, recorded on the ECG, precedes the mechanical events of the cardiac cycle. The small, rounded P wave of the ECG represents depolarization of the sinoatrial node (i.e., pacemaker of the heart), the atrial conduction tissue, and the atrial muscle mass. The QRS complex registers the depolarization of the ventricular conduction system and the ventricular muscle mass. The T wave on the ECG occurs during the last half of systole and represents repolarization of the ventricles.

**KEY POINTS**

**THE HEART**

- The heart is a four-chambered pump consisting of two atria (the right atrium, which receives blood returning to the heart from the systemic circulation, and the left atrium, which receives oxygenated blood from the lungs) and two ventricles (a right ventricle, which pumps blood to the lungs, and a left ventricle, which pumps blood into the systemic circulation). The heart valves control the direction of blood flow from the atria to the ventricles (the AV valves), from the right side of the heart to the lungs (pulmonic valve), and from the left side of the heart to the systemic circulation (aortic valve).

**Cardiac Cycle**

The term cardiac cycle is used to describe the rhythmic pumping action of the heart. The cardiac cycle is divided into two parts:

- **Systole**, the period during which the ventricles are contracting
- **Diastole**, the period during which the ventricles are relaxed and filling with blood

There are no valves at the atrial sites (i.e., venae cavae and pulmonary veins) where blood enters the heart. This means that excess blood is pushed back into the veins when the atria become distended. For example, the jugular veins typically become prominent in severe right-sided heart failure when they normally should be flat or collapsed. Likewise, the pulmonary venous system becomes congested when outflow from the left side of the heart is impeded.
represents closure of the aortic valve. This is caused by a short period of backflow of blood immediately before closure of the valve. The aorta is highly elastic and as such stretches during systole to accommodate the blood that is being ejected from the left heart. During diastole, recoil of the elastic fibers in the aorta serves to maintain the aortic pressure.

Diastole is marked by ventricular relaxation and filling. After closure of the semilunar valves, the ventricles continue to relax and fill with blood from the atria. This process is facilitated by the relaxation of the atrial muscles and the pressure gradient between the atria and the ventricles.

Aortic and pulmonic valves to snap shut. This event is marked by the second heart sound. The aortic pressure reflects changes in the ejection of blood from the left ventricle. There is a rise in pressure and stretching of the elastic fibers in the aorta as blood is ejected into the aorta at the onset of systole. The aortic pressure continues to rise and then begins to fall during the last quarter of systole as blood flows out of the aorta into the peripheral vessels. The incisura, or notch, in the aortic pressure tracing represents closure of the aortic valve. This is caused by a short period of backflow of blood immediately before closure of the valve. The aorta is highly elastic and as such stretches during systole to accommodate the blood that is being ejected from the left heart. During diastole, recoil of the elastic fibers in the aorta serves to maintain the aortic pressure.

Diastole is marked by ventricular relaxation and filling. After closure of the semilunar valves, the ventricles continue
to relax for another 0.03 to 0.06 second (referred to as the isovolumetric relaxation period). During this time, both the semilunar and AV valves remain closed, and the ventricular volume remains the same, as the ventricular pressure drops until it becomes less than the atrial pressure (see Fig. 29.10). As this occurs, the AV valves open and blood that has been accumulating in the atria during systole moves into the ventricle. Most of ventricular filling occurs during the first third of diastole, which is called the rapid filling period. During the middle third of diastole, inflow of blood into the ventricles constitutes a minimal amount. The last third of diastole is marked by atrial contraction, which gives an additional thrust to ventricular filling, which accounts for approximately 20% of the filling of the ventricles. When audible, the third heart sound is heard during the rapid filling period of diastole as blood flows into a distended or noncompliant ventricle. The fourth heart sound occurs during the last third of diastole as the atria contract.

During diastole, the ventricles increase their volume to approximately 120 mL (i.e., the end-diastolic volume). At the end of systole, approximately 40 to 50 mL of blood (i.e., the end-systolic volume) remains in the ventricles (see Fig. 29.10). The difference between the end-diastolic and end-systolic volumes (approximately 70 mL) is called the stroke volume. The ejection fraction, which is the stroke volume divided by the end-diastolic volume, represents the fraction or percentage of the end-diastolic volume that is ejected from the heart during systole. The left ventricular ejection fraction (normally about 55% to 75% when determined by echocardiography or angiocardiography) is frequently used to evaluate the prognosis of people with a variety of heart diseases.

Refer back to Mr. Brown whose ejection fraction is measured at 40%. This is below normal (normal is about 55% to 75%) and indicates a poor prognosis. In fact his low ejection fraction is a result of the complications of long-standing hypertension, and he has already been diagnosed with New York Heart Association stage II heart failure.

Atrial Filling and Contraction

There are three main atrial pressure waves that occur during the cardiac cycle—the a, c, and v waves. The a wave occurs during the last part of diastole and is caused by atrial contraction. The c wave occurs as the ventricles begin to contract, and their increased pressure causes the AV valves to bulge into the atria. The v wave occurs toward the end of systole when the AV valves are still closed and results from a slow buildup of blood in the atria. The right atrial pressure waves are transmitted to the internal jugular veins as pulsations. These pulsations can be observed visually and may be used to assess cardiac function. For example, exaggerated a waves occur when the volume of the right atrium is increased because of impaired emptying into the right ventricle.

Because there are no valves between the junctions of the central veins (i.e., venae cavae and pulmonary veins) and the atria, atrial filling occurs during both systole and diastole. During normal quiet breathing, right atrial pressure usually varies between −2 and + 2 mm Hg. It is this low atrial pressure that maintains the movement of blood from the systemic circulation into the right atrium and from the pulmonary veins into the left atrium.

Right atrial pressure is regulated by a balance between the ability of the heart to move blood out of the right heart and through the left heart into the systemic circulation and the tendency of blood to flow from the peripheral circulation into the right atrium. When the heart pumps strongly, right atrial pressure is decreased and atrial filling is enhanced. Right atrial pressure is also affected by changes in intrathoracic pressure. It is decreased during inspiration when intrathoracic pressure becomes more negative, and it is increased during coughing or forced expiration when intrathoracic pressure becomes more positive. Venous return is a reflection of the amount of blood in the systemic circulation that is available for return to the right heart and the force that moves blood back to the right side of the heart. Venous return is increased when the blood volume is expanded or when right atrial pressure falls, and it is decreased in hypovolemic shock or when right atrial pressure rises.

Although the main function of the atria is to store blood as it enters the heart, these chambers also act as pumps that aid in ventricular filling. This function becomes more important during periods of increased activity when the diastolic filling time is decreased because of an increase in heart rate or when heart disease impairs ventricular filling. In these two situations, the cardiac output would fall drastically were it not for the action of the atria. It has been estimated that atrial contraction can contribute as much as 20% to cardiac reserve during periods of increased need, while having little or no effect on cardiac output during rest.

Regulation of Cardiac Performance

The efficiency of the heart as a pump often is measured in terms of cardiac output or the amount of blood the heart pumps each minute. The cardiac output (CO) is the product of the stroke volume (SV) and the heart rate (HR) and can be expressed by the equation CO = SV × HR. The cardiac output varies with body size and the metabolic needs of the tissues. It increases with physical activity and decreases during rest and sleep. The average cardiac output in resting normal adults ranges from 4 to 6.0 L/minute. If a highly trained athlete is performing at an extreme exercise level, the heart may be required to pump four to six times this amount.

The cardiac reserve refers to the maximum percentage of increase in cardiac output that can be achieved above the normal resting level. The normal young adult has a cardiac reserve of approximately 300% to 400%. Cardiac performance is influenced by the work demands of the heart and the ability of the coronary circulation to meet its metabolic needs.
The heart’s ability to increase its output according to body needs mainly depends on four factors:

- **Preload**, or ventricular filling
- **Afterload**, or resistance to ejection of blood from the heart
- **Cardiac contractility**
- **Heart rate**

Heart rate and cardiac contractility are strictly cardiac factors, meaning they originate in the heart, although they are controlled by various neural and humoral mechanisms. Preload and afterload, on the other hand, are mutually dependent on the behavior of the heart and the vasculature. Not only do they determine the cardiac output, they are themselves determined by the cardiac output and certain vascular characteristics.

**Preload**

The preload represents the volume work of the heart. It is usually considered the end-diastolic pressure when the ventricle has been filled.\(^2\) It is called the preload because it is the work or load imposed on the heart before the contraction begins. Preload represents the amount of blood that the heart must pump with each beat. It is largely determined by the venous return to the heart and the accompanying stretch of the cardiac muscle fibers.

The increased force of contraction that accompanies an increase in ventricular end-diastolic volume is referred to as the Frank-Starling mechanism or Starling law of the heart (Fig. 29.11).\(^1\) The anatomic arrangement of the actin and myosin filaments in the myocardial muscle fibers is such that the tension or force of contraction depends on the degree to which the muscle fibers are stretched just before the ventricles begin to contract. The maximum force of contraction and cardiac output is achieved when venous return produces an increase in left ventricular end-diastolic filling (i.e., preload) such that the muscle fibers are stretched about two and one half times their normal resting length. When the muscle fibers are stretched to this degree, there is optimal overlap of the actin and myosin filaments needed for maximal contraction.

The Frank-Starling mechanism allows the heart to adjust its pumping ability to accommodate various levels of venous return. When a greater amount of blood flows into the ventricles, the cardiac muscle is stretched to a greater length. Cardiac output is less when decreased filling causes excessive overlap of the actin and myosin filaments or when excessive filling causes the filaments to be pulled too far apart.

**Afterload**

The afterload is the pressure in which the muscle exerts its contractile force in order to move blood into the aorta. It is called the afterload because it is the work presented to the heart after the contraction. The systemic arterial blood pressure is the main source of afterload work on the left heart, and the pulmonary arterial pressure is the main source of afterload work on the right heart. The afterload work of the left ventricle is also increased with narrowing (i.e., stenosis) of the aortic valve. For example, in the late stages of aortic stenosis, the left ventricle may need to generate systolic pressures up to 300 mm Hg to move blood through the diseased and narrow valve.\(^2,4\)

**Cardiac Contractility**

Cardiac contractility refers to the ability of the heart to change its force of contraction without changing its resting (i.e., diastolic) length. The contractile state of the myocardial muscle is determined by biochemical and biophysical properties that govern the actin and myosin interactions in the myocardial cells. It is strongly influenced by the number of calcium ions that are available to participate in the contractile process.

An inotropic influence is one that modifies the contractile state of the myocardium independent of the Frank-Starling mechanism (see Fig. 29.11, top curve). For example, sympathetic stimulation produces a positive inotropic effect by increasing the calcium that is available for interaction between the actin and myosin filaments. Hypoxia exerts a negative inotropic effect by interfering with the generation of adenosine triphosphate (ATP), which is needed for muscle contraction.

---

**FIGURE 29.11** • The Frank-Starling ventricular function curve in a normal heart. (Top) An increase in left ventricular end-diastolic (LVED) pressure produces an increase in cardiac output (curve B) by means of the Frank-Starling mechanism. The maximum force of contraction and increased stroke volume are achieved when diastolic filling causes the muscle fibers to be stretched about two and one half times their resting length. In curve A, an increase in cardiac contractility produces an increase in cardiac output without a change in LVED volume and pressure. (Bottom) Stretching of the actin and myosin filaments at the different LVED filling pressures.
Heart Rate
The heart rate determines the frequency with which blood is ejected from the heart. Therefore, as the heart rate increases, cardiac output tends to increase. As the heart rate increases, the time spent in diastole is reduced, and there is less time for the ventricles to fill. At a heart rate of 75 beats/minute, one cardiac cycle lasts 0.8 second, of which approximately 0.3 second is spent in systole and approximately 0.5 second in diastole. As the heart rate increases, the time spent in systole remains approximately the same, whereas that spent in diastole decreases. This leads to a decrease in stroke volume and, at high heart rates, a decrease in cardiac output. One of the dangers of ventricular tachycardia is a reduction in cardiac output because the heart does not have time to fill adequately.

IN SUMMARY
The heart is a four-chambered muscular pump that lies in the pericardial sac within the mediastinal space of the intrathoracic cavity. The wall of the heart is composed of an outer epicardium, which lines the pericardial cavity; a fibrous skeleton; the myocardium, or muscle layer; and the smooth endocardium, which lines the chambers of the heart. The four heart valves control the direction of blood flow.

The cardiac cycle describes the pumping action of the heart. It is divided into two parts: systole, during which the ventricles contract and blood is ejected from the heart, and diastole, during which the ventricles are relaxed and blood is filling the heart. The stroke volume (approximately 70 mL) represents the difference between the end-diastolic volume (approximately 120 mL) and the end-systolic volume (approximately 40 to 50 mL). The electrical activity of the heart, as represented on the ECG, precedes the mechanical events of the cardiac cycle. The heart sounds signal the closing of the heart valves during the cardiac cycle. Atrial contraction occurs during the last third of diastole. Although the main function of the atria is to store blood as it enters the heart, atrial contraction acts to increase cardiac output during periods of increased activity when the filling time is reduced or in disease conditions in which ventricular filling is impaired.

The heart’s ability to increase its output according to body needs depends on the preload, or filling of the ventricles (i.e., end-diastolic volume); the afterload, or resistance to ejection of blood from the heart; cardiac contractility, which determines the force of contraction; and the heart rate, which determines the frequency with which blood is ejected from the heart. The maximum force of cardiac contraction occurs when an increase in preload stretches muscle fibers of the heart to approximately two and one half times their resting length (i.e., Frank-Starling mechanism).

Refer back to Mr. Brown who has a high afterload due to high blood pressure. His left ventricle has been working harder than normal to overcome the increased resistance and eject blood into the aorta. This increased workload has stimulated muscle growth, leading to left ventricular hypertrophy (LVH). The thickened ventricular wall does not stretch easily during diastolic filling, so blood pools in the left atrium, leading to left atrial enlargement (LAE). LAE puts Mr. Brown at increased risk for arrhythmias.

The systemic circulation and control of blood flow
After completing this section of the chapter, you should be able to meet the following objectives:

- Compare the structure and function of arteries and veins.
- Use the equation blood pressure = cardiac output × peripheral vascular resistance to explain the regulation of arterial blood pressure.
- Define autoregulation and characterize mechanisms responsible for short-term and long-term regulation of blood flow.

The vascular system functions in the delivery of oxygen and nutrients and removal of waste products from the tissues. It consists of the arteries and arterioles, the capillaries, and the venules and veins. Although blood vessels of the vascular system are often compared with a system of rigid pipes and tubes, this analogy serves only as a starting point. Blood vessels are dynamic structures that constrict and relax to adjust blood pressure and flow to meet the varying needs of the many different tissue types and organ systems. Structures such as the heart, brain, liver, and kidneys require a large and continuous flow to carry out their vital functions. In other tissues such as the skin and skeletal muscle, the need for blood flow varies with the level of function. For example, there is a need for increased blood flow to the skin during fever and for increased skeletal muscle blood flow during exercise.

Blood Vessels
All blood vessels, except the capillaries, have walls composed of three layers, or coats, called tunicae (Fig. 29.12). The outermost layer of a vessel, called the tunica externa or tunica adventitia, is composed primarily of loosely woven collagen fibers that protect the blood vessel and anchor it to the surrounding structures. The middle layer, the tunica media, is largely a smooth muscle layer that constricts to regulate and control the diameter of the vessel. Larger arteries have
β-Adrenergic receptors are inhibitory in that they cause the channels to close and produce vasodilation. Calcium channel-blocking drugs cause vasodilation by blocking calcium entry through the calcium channels.

Smooth muscle contraction and relaxation also occur in response to local tissue factors such as lack of oxygen, increased hydrogen ion concentrations, and excess carbon dioxide. Nitric oxide (formerly known as the endothelial relaxing factor) acts locally to produce smooth muscle relaxation and regulate blood flow. These factors are discussed more fully in the section “Local and Humoral Control of Blood Flow.”

**KEY POINTS**

**THE VASCULAR SYSTEM AND CONTROL OF BLOOD FLOW**

- The vascular system, which consists of the arterial system (a high-pressure system delivering blood to the tissues), the venous system (a low-pressure system that collects blood from the capillaries), and the capillaries, functions in the delivery of oxygen and nutrients and in the removal of wastes from the tissues.

- Local control of blood flow is regulated by mechanisms that match blood flow to the metabolic needs of the tissue. Over the short term, the tissues autoregulate flow through the synthesis of vasodilators and vasoconstrictors derived from the tissue, smooth muscle, or endothelial cells; over the long term, blood flow is regulated by creation of a collateral circulation.

**Arterial System**

The arterial system consists of the large- and medium-sized arteries and the arterioles. Arteries are thick-walled vessels with large amounts of elastic fibers. The elasticity of these vessels allows them to stretch during systole, when the heart contracts and blood enters the circulation, and to recoil during diastole, when the heart relaxes. The arterioles, which are predominantly smooth muscle, serve as resistance vessels for the circulatory system. They act as control valves through which blood is released as it moves into the capillaries. Changes in the activity of sympathetic fibers that innervate these vessels cause them to constrict or to relax as needed to maintain blood pressure.

**Arterial Pressure Pulsations**

The delivery of blood to the tissues of the body depends on pressure pulsations or waves of pressure that are generated by the intermittent ejection of blood from the left ventricle into the distensible aorta and large arteries of the arterial system. The arterial pressure pulse represents the energy that is transmitted from molecule to molecule along the length of the arterial system, causing wave-like depolarizations that travel down the arterial system and are transmitted to the capillaries.
of the vessel (Fig. 29.13). In the aorta, this pressure pulse is transmitted at a velocity of 4 to 6 m/second, which is approximately 20 times faster than the flow of blood. Therefore, the pressure pulse has no direct relation to blood flow and could occur if there was no flow at all. When taking a pulse, it is the pressure pulses that are felt, and it is the pressure pulses that produce the Korotkoff sounds heard during blood pressure measurement. The tip or maximum deflection of the pressure pulsation coincides with the systolic blood pressure, and the minimum point of deflection coincides with the diastolic pressure. The pulse pressure is the difference between systolic and diastolic pressure. If all other factors are equal, the magnitude of the pulse pressure reflects the volume of blood ejected from the left ventricle in a single beat.

Both the pressure values and the conformation of the pressure wave change as it moves through the peripheral arteries, such that pulsations in the large arteries are even greater than those in the aorta (see Fig. 29.13). In other words, systolic pressure and pulse pressure are higher in large arteries than in the aorta. The increase in pulse pressure in the “downstream” arteries is due to the fact that immediately after ejection from the left ventricle, the pressure wave travels at a higher velocity than the blood itself, augmenting the downhill pressure. Furthermore, at branch points of arteries, pressure points are reflected backward, which also tends to augment pressure at those sites. With peripheral arterial disease, there is a delay in the transmission of the reflected wave so that the pulse decreases rather than increases in amplitude.

After its initial amplification, the pressure pulse becomes smaller and smaller as it moves through the smaller arteries and arterioles, until it disappears almost entirely in the capillaries. This damping of the pressure pulse is caused by the resistance and distensibility characteristics of these vessels. The increased resistance of these small vessels impedes the transmission of the pressure waves. However, their distensibility is great enough that any small change in flow does not cause a pressure change. Although the pressure pulses usually are not transmitted to the capillaries, there are situations in which this does occur. For example, injury to a finger or other area of the body often results in a throbbing sensation. In this case, extreme dilation of the small vessels in the injured area produces a reduction in the dampening of the pressure pulse. Capillary pulsations also occur in conditions that cause exaggeration of aortic pressure pulses, such as aortic regurgitation or patent ductus arteriosus.

**Venous System**

The venous system is a low-pressure system that returns blood to the heart. The venules collect blood from the capillaries, and the veins transport blood back to the right heart. Because blood from the systemic veins flows into the right atrium of the heart, the pressure in the right atrium is called the central venous pressure. Right atrial pressure is regulated by the ability of the right ventricle to pump blood into the lungs and the tendency of blood to flow from the peripheral veins into the right atrium. The normal right atrial pressure is about 0 mm Hg, which is equal to atmospheric pressure. It can increase to 20 to 30 mm Hg in conditions such as right heart failure and the rapid transfusion of blood at a rate that greatly increases total blood volume and causes excessive quantities of blood to attempt to flow into the heart from the systemic veins.

The veins and venules are thin-walled, distensible, and collapsible vessels. The veins are capable of enlarging and storing large quantities of blood, which can be made available to the circulation as needed. Even though the veins are thin walled, they are muscular. This allows them to contract or expand to accommodate varying amounts of blood. Veins are innervated by the sympathetic nervous system. When blood is lost from the circulation, the veins constrict as a means of maintaining intravascular volume.

Valves in the veins of extremities prevent retrograde flow (Fig. 29.14). Thus, with the help of skeletal muscles that surround and intermittently compress the leg veins in a milking manner, blood is moved forward to the heart. This pumping action is known as the venous or muscle pump. It facilitates blood flow return at low pressure back to the heart against gravity. There are no valves in the abdominal or thoracic veins. Therefore, pressure in the abdominal and thoracic cavities, respectively, heavily influence blood flow in these veins.

Because the venous system is a low-pressure system, blood flow must oppose the effects of gravity. In a person in the standing position, the weight of the blood in the vascular column causes an increase of 1 mm Hg in pressure for every 13.6 mm of distance below the level of the heart. Were it not for the valves in the veins and the action of the skeletal muscles, the venous pressure in the feet would be about...
UNIT VIII Disorders of Cardiovascular Function

+90 mm Hg in the standing adult. Gravity has no effect on the venous pressure in a person in the recumbent position because the blood in the veins is then at the level of the heart.

**Local and Humoral Control of Blood Flow**

Tissue blood flow is regulated on a minute-to-minute basis in relation to tissue needs and on a longer-term basis through the development of collateral circulation. Neural mechanisms regulate the cardiac output and blood pressure needed to support these local mechanisms.

**Short-Term Autoregulation**

Local control of blood flow is governed largely by the nutritional needs of the tissue. For example, blood flow to organs such as the heart, brain, and kidneys remains relatively constant, although blood pressure may vary over a range of 60 to 180 mm Hg. The ability of the tissues to maintain constant changes in perfusion pressure is called autoregulation. Autoregulation of blood flow is mediated by changes in blood vessel tone due to changes in flow through the vessel or by local tissue factors, such as lack of oxygen or accumulation of tissue metabolites (i.e., potassium, lactic acid, or adenosine, which is a breakdown product of ATP). For example, a change in systemic arterial pressure (e.g., such as hypotension during circulatory shock) leads to autoregulation in organs to ensure adequate blood flow and oxygen delivery.

**Reactive Hyperemia.** An increase in local blood flow following a brief period of ischemia is called reactive hyperemia. The ability of tissues to increase blood flow in situations of increased activity, such as exercise, is called functional hyperemia. When the blood supply to an area has been occluded and then restored, local blood flow through the tissues increases within seconds to restore the metabolic equilibrium of the tissues. The transient redness seen on an arm after leaning on a hard surface is an example of reactive hyperemia. Local control mechanisms rely on a continuous flow from the main arteries. Therefore, hyperemia cannot occur when the arteries that supply the capillary beds are narrowed. For example, if a major coronary artery becomes occluded, the opening of channels supplied by that vessel cannot restore blood flow.

**Endothelial Control of Vascular Function.** One of the important functions of the endothelial cells lining the arterioles and small arteries is the synthesis and release of factors that control vessel dilation. Intact endothelium is able to produce a factor that causes relaxation of vascular smooth muscle. Originally this factor was called endothelium-derived relaxing factor; it is now known as nitric oxide. The normal endothelium maintains a continuous release of nitric oxide, which is formed from L-arginine and oxygen through the action of an enzyme called nitric oxide synthase (Fig. 29.15). The production of nitric oxide can be stimulated by a variety of endothelial agonists, including acetylcholine, bradykinin, histamine, and thrombin. Shear stress on the endothelium resulting from an increase in blood flow or blood pressure also stimulates nitric oxide production and vessel relaxation. Nitric oxide also inhibits platelet aggregation and secretion of platelet contents, many of which cause vasoconstriction. Nitric oxide is released into the vessel lumen (to inactivate platelets) and away from the lumen.
Long-Term Regulation of Blood Flow

Long-term regulation allows a more complete control of blood flow compared to short-term regulation. One way to regulate blood flow is to change the amount of vascularity over a prolonged period of time. This process is called angiogenesis. If the metabolism in the tissue is increased for a long period of time, vascularity increases and vice versa. There is actual physical reconstruction of the tissue vasculature to meet the metabolic need of the tissue. This regeneration occurs much better in younger tissue compared to older tissue. In addition, vascular endothelial growth factor (VEGF), angiotensin II, endothelin-1, and endostatin have been isolated in tissues that have insufficient blood supply. These growth factors cause new vessels to sprout and grow. Blood vessels can also disappear due to certain other substances, such as angiostatin and endostatin, in which the exact physiological mechanism is unknown. Oxygen also plays a role in the long-term regulation of blood flow. For example, if the atmospheric oxygen is low, then the vascularity increases to compensate for the low oxygen. This is seen in animals that live in higher altitude where oxygen levels are low.

Furthermore, collateral circulation is a mechanism for the long-term regulation of local blood flow. In the heart and other vital structures, anastomotic channels exist between some of the smaller arteries. These channels permit perfusion of an area by more than one artery. When one artery becomes occluded, these anastomotic channels increase in size, allowing blood from a patent artery to perfuse the area supplied by the occluded vessel. For example, people with extensive obstruction of a coronary blood vessel may rely on collateral circulation to meet the oxygen needs of the myocardial tissue normally supplied by that vessel. As with other long-term compensatory mechanisms, the recruitment of collateral circulation is most efficient when obstruction to flow is gradual rather than sudden.

Humoral Control of Vascular Function

Humoral control of blood flow involves the effect of vasodilator and vasoconstrictor substances in the blood. Some of these substances are formed by special glands and transported in the blood throughout the entire circulation. Others are formed in local tissues and aid in the local control of blood flow. Among the most important of the humoral factors are norepinephrine and epinephrine, angiotensin II, histamine, serotonin, bradykinin, and the prostaglandins.

Norepinephrine and Epinephrine. Norepinephrine is an especially powerful vasoconstrictor hormone. Epinephrine is less so and in some tissues (e.g., skeletal muscle) even causes mild vasodilation. Stimulation of the sympathetic nervous system during stress or exercise causes local constriction of veins and arterioles because of the release of norepinephrine from sympathetic nerve endings. In addition, sympathetic stimulation causes the adrenal medulla to secrete both norepinephrine and epinephrine into the blood. These hormones then circulate in the blood, causing direct sympathetic stimulation of blood vessels in all parts of the body.

Angiotensin II. Angiotensin II is another powerful vasoconstrictor substance. Angiotensin II is produced as a part of the renin–angiotensin–aldosterone system and normally acts on many arterioles simultaneously to increase the PVR, thereby increasing the arterial blood pressure.

Histamine. Histamine has a powerful vasodilator effect on arterioles and has the ability to increase capillary permeability, allowing leakage of both fluid and plasma proteins into the tissues. Histamine is largely derived from mast cells in injured tissues and basophils in the blood. In certain tissues, such as skeletal muscle, the activity of the mast cells is mediated by the sympathetic nervous system. When sympathetic control is withdrawn, the mast cells release histamine.

Serotonin. Serotonin is liberated from aggregating platelets during the clotting process. It causes vasoconstriction and plays a major role in control of bleeding. Serotonin is found in brain and lung tissues, and there is some speculation that it may be involved in the vascular spasm associated with some allergic pulmonary reactions and migraine headaches.

Bradykinin. The kinins (i.e., kallidins and bradykinin) are liberated from the globulin kininogen, which is present in body fluids. Bradykinin causes intense dilation of arterioles, increased capillary permeability, and constriction of venules. It is thought that the kinins play special roles in regulating blood flow and capillary leakage in inflamed tissues. It is also believed that bradykinin helps to regulate blood flow in the skin as well in the salivary and gastrointestinal glands.

Prostaglandins. Prostaglandins are synthesized from constituents of the cell membrane (i.e., the long-chain fatty acid arachidonic acid). Tissue injury incites the release of arachidonic acid from the cell membrane, which initiates prostaglandin synthesis. There are several prostaglandins (e.g., E2, F2, D), which are subgrouped according to their solubility; some produce vasoconstriction and some produce vasodilation. As a rule of thumb, those in the E group are vasodilators, and those in the F group are vasoconstrictors. The corticosteroid hormones produce an anti-inflammatory response by blocking the release of arachidonic acid, preventing prostaglandin synthesis.
IN SUMMARY

The walls of all blood vessels, except the capillaries, are composed of three layers: the tunica externa, tunica media, and tunica intima. The layers of the vessel vary with its function. Arteries are thick-walled vessels with large amounts of elastic fibers. The walls of the arterioles, which control blood pressure, have large amounts of smooth muscle. Veins are thin-walled, distensible, and collapsible vessels. Venous flow is designed to return blood to the heart. It is a low-pressure system and relies on venous valves and the action of muscle pumps to offset the effects of gravity.

The delivery of blood to the tissues of the body depends on pressure pulses that are generated by the intermittent ejection of blood from the left ventricle into the distensible aorta and large arteries of the arterial system. The combination of distensibility of the arteries and their resistance to flow reduces the pressure pulsations so that constant blood flow occurs by the time blood reaches the capillaries.

The mechanisms that control local blood flow are designed to ensure adequate delivery of blood to the capillaries in the microcirculation, where the exchange of cellular nutrients and wastes occurs. Local control is governed largely by the needs of the tissues and is regulated by local tissue factors such as lack of oxygen and the accumulation of metabolites. Reactive hyperemia is a local increase in blood flow that occurs after a temporary occlusion of blood flow. It is a compensatory mechanism that decreases the oxygen debt of the deprived tissues. Long-term regulation of blood flow includes angiogenesis, vascular endothelial growth factor, fibroblast growth factor and angiotensin which increase tissue vascularity, while angiostatin and endostatin have been found to dissolve blood vessels. Collateral circulation improves local blood flow by the development of collateral vessels.1,2 The endothelial relaxing factor (mainly nitric oxide) and humoral factors, such as norepinephrine and epinephrine, angiotensin II, histamine, serotonin, bradykinin, and the prostaglandins, contribute to the regulation of blood flow.

THE MICROCIRCULATION AND LYMPHATIC SYSTEM

After completing this section of the chapter, you should be able to meet the following objectives:

- Define the term microcirculation.
- Describe the structure and function of the capillaries.
- Explain the forces that control the fluid exchange between the capillaries and the interstitial spaces.

The term microcirculation refers to the functions of the smallest blood vessels, the capillaries and the neighboring lymphatic vessels, which transport nutrients to tissues and remove excreta from the cells.

Structure and Function of the Microcirculation

The structures of the microcirculation include the arterioles, capillaries, and venules. Blood enters the microcirculation through an arteriole, passes through the capillaries, and leaves through a small venule. The metarterioles serve as thoroughfare channels that link arterioles and capillaries (Fig. 29.16). Small cuffs of smooth muscle, the precapillary sphincters, are positioned at the arterial end of the capillary. The smooth muscle tone of the arterioles, venules, and precapillary sphincters serves to control blood flow through the capillary bed. Depending on venous pressure, blood flows through the capillary channels when the precapillary sphincters are open.

Capillary Structure and Function

Capillaries are microscopic vessels that connect the arterial and venous segments of the circulation. In each person, there are approximately 10 billion capillaries, with a total surface area of 500 to 700 m². The capillary wall is composed of a single layer of endothelial cells and their basement membrane (Fig. 29.17). The endothelial cells form a tube just large enough to allow the passage of red blood cells, one at a time.

Water-filled junctions, called the capillary pores, join the capillary endothelial cells and provide a pathway for passage of substances through the capillary wall. The size of the capillary pores varies with capillary function. In the brain, the endothelial cells are joined by tight junctions that form the blood–brain barrier. This prevents substances that would alter neural excitability from leaving the capillary. In organs that process blood...
Control of Blood Flow in the Microcirculation

Blood flow through capillary channels, designed for exchange of nutrients and metabolites, is called nutrient flow. In some parts of the microcirculation, blood flow bypasses the capillary bed, moving through a connection called an arteriovenous shunt, which directly connects an arteriole and a venule. This type of blood flow is called nonnutrient flow because it does not allow for nutrient exchange. Nonnutrient channels are common in the skin and are important in terms of heat exchange and temperature regulation.

Capillary–Interstitial Fluid Exchange

The hydrostatic and osmotic pressures of the capillary and interstitial fluids, as well as the permeability of the capillary wall, largely control the direction and magnitude of fluid movement across the capillary wall. The direction of fluid movement can either be into or out of the capillary. When net fluid movement is out of the capillary into the interstitial spaces, it is called filtration. When net movement is from the interstitium into the capillary, it is called absorption (Fig. 29.18).

The capillary hydrostatic pressure represents the fluid pressure that tends to push water and its dissolved substances through the capillary pores into the interstitium. The osmotic pressure caused by the plasma proteins in the blood tends to pull fluid from the interstitial spaces back into the capillary. This pressure is termed colloidal osmotic pressure to differentiate the osmotic effects of the plasma proteins, which are...
suspended colloids, from the osmotic effects of substances such as sodium and glucose, which are dissolved crystalloids. Capillary permeability controls the movement of water and substances, such as the plasma proteins that influence osmotic pressure, into the interstitial spaces. Also important to this exchange mechanism is the lymphatic system, which removes excess fluid and osmotically active proteins and large particles from the interstitial spaces and returns them to the circulation.

**Hydrostatic Forces**

The capillary hydrostatic pressure is the principal force in capillary filtration. Both the arterial and venous pressures (the capillaries being interspersed between the arteries and veins) determine the hydrostatic pressure (blood pressure) within the capillaries. An increase in small artery and arterial pressure elevates capillary hydrostatic pressure. However, a reduction in each of these pressures has the opposite effect. A change in venous pressure has a greater effect on the capillary hydrostatic pressure than does the same change in arterial pressure. About 80% of increased venous pressure, such as that caused by venous thrombosis or congestive heart failure, is transmitted back to the capillary. The previously discussed effects on gravity on venous pressure also affect capillary hydrostatic pressure. When a person stands, the hydrostatic pressure is greater in the legs and lower in the head.

The interstitial hydrostatic pressure is the pressure exerted by the interstitial fluids outside the capillary. It can be positive or negative. A positive interstitial fluid pressure opposes capillary filtration, and a negative interstitial fluid pressure increases the movement of fluid out of the capillary into the interstitium. In the normal nonedematous state, the interstitial hydrostatic pressure is close to zero or slightly negative (~1 to ~4 mm Hg) and has very little effect on capillary filtration or outward movement of fluid.

**Osmotic Forces**

The key factor that restrains fluid loss from the capillaries is the colloidal osmotic pressure (approximately 28 mm Hg) generated by the plasma proteins. The plasma proteins are large molecules that disperse in the blood and occasionally escape into the tissue spaces. Because the capillary membrane is almost impermeable to the plasma proteins, these particles exert an osmotic force that pulls fluid into the capillary and offsets the pushing force of the capillary filtration pressure.

The plasma contains a mixture of plasma proteins, including albumin, globulins, and fibrinogen. Albumin, which is the smallest and most abundant of the plasma proteins, accounts for approximately 70% of the total osmotic pressure. It is the number, not the size, of the particles in solution that controls the osmotic pressure. One gram of albumin (molecular weight of 69,000) contains almost six times as many molecules as 1 g of fibrinogen (molecular weight of 400,000). (Normal values for the plasma proteins are albumin, 4.5 g/dL; globulins, 2.5 g/dL; and fibrinogen, 0.3 g/dL.)

Although the size of the capillary pores prevents most plasma proteins from leaving the capillary, small amounts escape into the interstitial spaces and exert an osmotic force that tends to pull fluid from the capillary into the interstitium. This amount is increased in conditions such as inflammation in which an increase in capillary permeability allows plasma proteins to escape into the interstitium. The lymphatic system is responsible for removing proteins from the interstitium. In the absence of a functioning lymphatic system, interstitial colloidal osmotic pressure increases, causing fluid to accumulate. Normally, a few white blood cells, plasma proteins, and other large molecules enter the interstitial spaces. These cells and molecules, which are too large to reenter the capillary, rely on the loosely structured wall of the lymphatic vessels for return to the vascular compartment.

**Balance of Hydrostatic and Osmotic Forces**

Normally, the movement of fluid between the capillary bed and the interstitial spaces is continuous. As Earnest H. Starling pointed out, a state of equilibrium exists as long as equal amounts of fluid enter and leave the interstitial spaces. This is referred to as “Starling forces” and is illustrated in Figure 29.19. In the diagram, the hydrostatic pressure at the arterial end of the capillary is higher than at the venous end. The pushing force of the capillary hydrostatic pressure on the arterial end of the capillary, along with the pulling effects of the interstitial colloidal osmotic pressure, contributes to the net outward movement of fluid. The capillary colloidal osmotic pressure and opposing interstitial osmotic pressure determine the reabsorption of fluid at the venous end of the capillary. A slight imbalance in forces causes slightly more filtration of fluid into interstitial spaces than absorption back into the capillary. It is this fluid that is returned to the circulation by the lymphatic system.

![Figure 29.19 - Capillary–interstitial fluid exchange equilibrium](image-url)
The Lymphatic System

The lymphatic system represents an accessory route through which fluid can flow into the blood from interstitial spaces. This system, commonly called the lymphatics, serves almost all body tissues, except cartilage, bone, epithelial tissue, and tissues of the central nervous system (CNS). However, even most of these tissues have prelymphatic channels that eventually flow into areas supplied by the lymphatics. Lymph is derived from interstitial fluids that flow through the lymph channels. It contains plasma proteins and other osmotically active particles that rely on the lymphatics for movement back into the circulatory system. The lymphatic system is also the main route for absorption of nutrients, particularly fats, from the gastrointestinal tract. The lymphatic system also filters the fluid at the lymph nodes and removes foreign particles such as bacteria. When lymph flow is obstructed, a condition called lymphedema occurs. Involvement of lymphatic structures by malignant tumors and removal of lymph nodes at the time of cancer surgery are common causes of lymphedema.

The lymphatic system is made up of vessels similar to those of the circulatory system. These vessels commonly travel along with an arteriole or venule or with its companion artery and vein. The terminal lymphatic vessels are made up of a single layer of connective tissue with an endothelial lining and resemble blood capillaries. The lymphatic vessels lack tight junctions and are loosely anchored to the surrounding tissues by fine filaments (Fig. 29.20). The loose junctions permit the entry of large particles, and the filaments hold the vessels open under conditions of edema when the pressure of the surrounding tissues would otherwise cause them to collapse. The lymph capillaries drain into larger lymph vessels that ultimately empty into the right and left thoracic ducts (Fig. 29.21). The thoracic ducts empty into the circulation at the junctions of the subclavian and internal jugular veins. The total amount of lymph transported is 2 to 3L/day in a healthy person.

Although the divisions are not as distinct as in the circulatory system, the larger lymph vessels show evidence of having intimal, medial, and adventitial layers similar to blood vessels. The intima of these channels contains elastic tissue and an endothelial layer, and the larger collecting lymph vessels contain smooth muscle in their medial layer. Contraction of this smooth muscle assists in propelling lymph toward the thorax. External compression of the lymph channels by pulsating blood vessels in the vicinity and active and passive movements of body parts also aid in forward propulsion of lymph. The interstitial fluid pressure and the activity of lymph pumps determine the rate of flow (approximately 120 mL/hour) through the lymphatic system via all of the various lymph channels.

IN SUMMARY

Exchange of fluids between the vascular compartment and the interstitial spaces occurs at the capillary level. The capillary hydrostatic pressure pushes fluids out of the capillaries, and the colloidal osmotic pressure exerted by the plasma proteins pulls fluids back into the capillaries. Albumin, which is the smallest and most abundant of the plasma proteins, provides the major osmotic force for return of fluid to the vascular compartment. Normally, slightly more fluid leaves the capillary bed than can be reabsorbed. This excess fluid is returned to the circulation by way of the lymphatic channels.

NEURAL CONTROL OF CIRCULATORY FUNCTION

After completing this section of the chapter, you should be able to meet the following objectives:

- Relate the performance of baroreceptors and chemoreceptors in the control of cardiovascular function.
- Describe the distribution of the sympathetic and parasympathetic nervous systems in the innervation of the circulatory system and their effects on heart rate and cardiac contractility.
- Relate the role of the CNS in terms of regulating circulatory function.

The neural control centers for the integration and modulation of cardiac function and blood pressure are located bilaterally in the medulla oblongata. The medullary cardiovascular neurons...
are grouped into three distinct pools that lead to sympathetic innervation of the heart and blood vessels and parasympathetic innervation of the heart. The first two, which control sympathetic-mediated acceleration of heart rate and blood vessel tone, are called the vasomotor center. The third, which controls parasympathetic-mediated slowing of heart rate, is called the cardioinhibitory center. These brain stem centers receive information from many areas of the nervous system, including the hypothalamus. The arterial baroreceptors and chemoreceptors provide the medullary cardiovascular center with continuous information regarding changes in blood pressure.

**Autonomic Nervous System Regulation**

The neural control of the circulatory system occurs primarily through the sympathetic and parasympathetic divisions of the autonomic nervous system (ANS). The ANS contributes to the control of cardiovascular function through modulation of cardiac (i.e., heart rate and cardiac contractility) and vascular (i.e., PVR) functions.

**Autonomic Regulation of Cardiac Function**

The heart is innervated by the parasympathetic and sympathetic nervous systems. Parasympathetic innervation of the heart is achieved by means of the vagus nerve. The parasympathetic outflow to the heart originates from the vagal nucleus in the medulla. The axons of these neurons pass to the heart in the cardiac branches of the vagus nerve. The effect of vagal stimulation on heart function is largely limited to heart rate, with increased vagal activity producing a slowing of the pulse. Sympathetic outflow to the heart and blood vessels arises from neurons located in the reticular formation of the brain stem. The axons of these neurons exit the thoracic segments of the spinal cord to synapse with the postganglionic neurons that innervate the heart. Cardiac sympathetic fibers are widely distributed to the sinoatrial and AV nodes and the myocardium. Increased sympathetic activity produces an increase in the heart rate and the velocity and force of cardiac contraction.

**Autonomic Regulation of Vascular Function**

The sympathetic nervous system serves as the final common pathway for controlling the smooth muscle tone of the blood vessels. Most of the sympathetic preganglionic fibers that control vessel function originate in the vasomotor center of the brain stem, travel down the spinal cord, and exit in the thoracic and lumbar (T1–L2) segments. The sympathetic neurons that supply the blood vessels maintain them in a state of tonic activity, so that even under resting conditions, the blood vessels are partially constricted. Vessel constriction and relaxation are accomplished by altering this basal input. Increasing sympathetic activity causes constriction of some vessels, such as those of the skin, the
gastrointestinal tract, and the kidneys. Blood vessels in skeletal muscle are supplied by both vasoconstrictor and vasodilator fibers. Activation of sympathetic vasodilator fibers causes vessel relaxation and provides the muscles with increased blood flow during exercise. Although the parasympathetic nervous system contributes to the regulation of heart function, it has little or no control over blood vessels.

**Autonomic Neurotransmitters**

The actions of the ANS are mediated by chemical neurotransmitters. Acetylcholine is the postganglionic neurotransmitter for parasympathetic neurons, and norepinephrine is the main neurotransmitter for postganglionic sympathetic neurons. Sympathetic neurons also respond to epinephrine, which is released into the bloodstream by the adrenal medulla. The neurotransmitter dopamine can also act as a neurotransmitter for some sympathetic neurons.

**Central Nervous System Responses**

It is not surprising that the CNS, which plays an essential role in regulating vasomotor tone and blood pressure, would have a mechanism for controlling the blood flow to the cardiovascular centers that control circulatory function. When the blood flow to the brain has been sufficiently interrupted to cause ischemia of the vasomotor center, these vasomotor neurons become strongly excited. This causes massive vasoconstriction as a means of raising the blood pressure to levels as high as 270 mm Hg for as long as 10 minutes. It is thought that the buildup of lactic acid and other acidic substances in the vasomotor center also contributes to the CNS ischemic response as a last-ditch stand to preserve the blood flow to vital brain centers. It does not become activated until blood pressure has fallen to at least 60 mm Hg, and it is most effective in the range of 15 to 20 mm Hg. If the cerebral circulation is not reestablished within 3 to 10 minutes, the neurons of the vasomotor center cease to function. As a result, the tonic impulses to the blood vessels stop and the blood pressure falls precipitously.

The Cushing reaction is a special type of CNS response resulting from an increase in intracranial pressure. When the intracranial pressure rises to levels that equal intra-arterial pressure, blood vessels to the vasomotor center become compressed, initiating the CNS ischemic response. The purpose of this reflex is to produce a rise in arterial pressure to levels above intracranial pressure so that the blood flow to the vasomotor center can be reestablished. Should the intracranial pressure rise to the point that the blood supply to the vasomotor center becomes inadequate, vasoconstrictor tone is lost, and the blood pressure begins to fall. The elevation in blood pressure associated with the Cushing reflex is usually of short duration and should be considered a protective homeostatic mechanism. It helps protect the vital centers of the brain from nutrition loss if the CNS fluid rises high enough to compress the arterial arteries. The brain and other cerebral structures are located within the rigid confines of the skull; with no room for expansion. Therefore, any increase in intracranial pressure tends to compress the blood vessels that supply the brain.

**IN SUMMARY**

The neural control centers for the regulation of cardiac function and blood pressure are located in the reticular formation of the lower pons and medulla of the brain stem, where the integration and modulation of ANS responses occur. These brain stem centers receive information from many areas of the nervous system, including the hypothalamus. Both the parasympathetic and sympathetic nervous systems innervate the heart. The parasympathetic nervous system functions in regulating heart rate through the vagus nerve, with increased vagal activity producing a slowing of heart rate. The sympathetic nervous system has an excitatory influence on heart rate and contractility, and it serves as the final common pathway for controlling the smooth muscle tone of the blood vessels.

**REVIEW EXERCISES**

1. In people with atherosclerosis of the coronary arteries, symptoms of myocardial ischemia do not usually occur until the vessel has been 75% occluded.
   A. Use the Poiseuille law to explain.
   B. Using information related to cross-sectional area and velocity of flow, explain why there is stasis of blood flow with the tendency to form clots in aneurysms with a large cross-sectional area.

2. Once an arterial aneurysm has begun to form, it continues to enlarge as the result of the increased tension in its wall.
   A. Explain the continued increase in size using the law of Laplace.
   B. Using information related to cross-sectional area and velocity of flow, explain why there is
   C. The effect of an increase in heart rate on the time spent in diastole
   D. The effect of an increase in the isovolumetric relaxation period on the diastolic filling of the ventricle

Continued
4. Use the Frank-Starling ventricular function curve depicted in Figure 29.11 to explain the changes in cardiac output that occur with changes in respiratory effort.

A. What happens to cardiac output during increased inspiratory effort in which a marked decrease in intrathoracic pressure produces an increase in venous return to the right heart?

B. What happens to cardiac output during increased expiratory effort in which a marked increase in intrathoracic pressure produces a decrease in venous return to the right heart?

C. Given these changes in cardiac output that occur during increased respiratory effort, what would you propose as one of the functions of the Frank-Starling curve?

Blood flow in the arterial and venous systems depends on a system of patent blood vessels and adequate perfusion pressure. Unlike disorders of the respiratory system or central circulation that cause hypoxia and impair oxygenation of tissues throughout the body, the effects of blood vessel disease usually are limited to local tissues supplied by a particular vessel or group of vessels.

With arterial disorders, there is decreased blood flow to the tissues along with impaired delivery of oxygen and nutrients. With venous disorders, there is interference with the outflow of blood and removal of waste products. Disturbances in blood flow can result from pathologic changes in the vessel wall (i.e., atherosclerosis and vasculitis), acute vessel obstruction due to thrombus or embolus, vasospasm (i.e., Raynaud phenomenon), or abnormal vessel dilation (i.e., arterial aneurysms or varicose veins).
The heart is the pump of the cardiovascular system. It pumps blood via the blood vessels so that blood is transported throughout the body. The walls of all blood vessels, except the very smallest, are composed of three distinct layers—an outer layer of loosely woven collagen tissue, the tunica externa, which is composed of loose connective tissue; a middle layer, the tunica media, which consists primarily of circumferentially arranged layers of smooth muscle cells (SMCs); and an inner layer, the tunica intima, which consists of a single layer of endothelial cells that line the lumen of the vessel, and the underlying subendothelial connective tissue (Fig. 30.1). Table 30.1 describes the structure and function of the blood vessels. As the main cellular components of the blood vessel wall, the endothelial and smooth muscle cells play an important role in the pathogenesis of many disorders of the arterial circulation. Figure 30.2 illustrates the microanatomy of the vein, artery, and capillary beds.

**Endothelial Cells**

Endothelial cells form a continuous lining for the entire vascular system called the endothelium. The endothelium is made up of approximately 60,000 miles of squamous epithelium that lines the various-sized vessels. Endothelium is a versatile, multifunctional tissue that plays an active role in controlling vascular function. This semipermeable membrane controls the transfer of molecules across the vascular wall and has an essential role in homeostasis. The endothelium also plays a role in the control of platelet adhesion and blood clotting, modulation of blood flow and vascular resistance, metabolism of hormones, regulation of immune and inflammatory reactions, and elaboration of factors that influence the growth of other cell types, particularly vascular SMCs.

Structurally intact endothelial cells respond to various abnormal stimuli by adjusting their usual functions and by expressing newly acquired functions. The term endothelial dysfunction describes several types of potentially reversible changes in endothelial function that occur in response to environmental stimuli. Inducers of endothelial dysfunction include cytokines and bacterial, viral, and...
parasitic products that cause inflammation; hemodynamic stresses and lipid products that are critical to the pathogenesis of atherosclerosis; and hypoxia. Dysfunctional endothelial cells, in turn, produce other cytokines, growth factors, procoagulant or anticoagulant substances, and a variety of other biologically active products. They also influence the reactivity of underlying SMCs through production of both relaxing factors (e.g., nitric oxide) and contracting factors (e.g., endothelins).

**Vascular Smooth Muscle Cells**

Vascular SMCs, which form the predominant cellular layer in the tunica media, produce vasoconstriction and/or dilation of blood vessels. A network of vasomotor nerves of the sympathetic component of the autonomic nervous system supplies the smooth muscle in the blood vessels. These nerves and circulating hormones are responsible for vasoconstriction of the vessel walls. Because they do not enter the tunica media of the blood vessel, the nerves do not synapse directly on the SMCs. Instead, they release the neurotransmitter, norepinephrine, which diffuses into the media and acts on the nearby SMCs. The resulting impulses are propagated along the SMCs through their gap junctions, causing contraction of the entire muscle cell layer and thus reducing the radius of the vessel lumen. This in turn increases the systemic circulation.

Vascular SMCs also synthesize collagen, elastin, and other components of the extracellular matrix (ECM); elaborate growth factors and cytokines; and after vascular injury migrate into the intima and proliferate. Thus, SMCs are important in both normal vascular repair and pathologic processes such as atherosclerosis. Growth promotes and inhibitors stimulate the migratory and proliferative activities of vascular SMCs. Promoters include platelet-derived growth factor, thrombin, fibroblast growth factor, and cytokines such as interferon gamma and interleukin-1. Growth inhibitors include nitric oxide. Other regulators include the renin–angiotensin system (angiotensin II) and the catecholamines.
The walls of blood vessels are composed of three layers—an outer layer of loosely woven collagen tissue, a middle layer of vascular smooth muscle, and an inner layer of endothelial cells. The endothelium controls the transfer of molecules across the vascular wall and plays a role in the control of platelet adhesion and blood clotting, modulation of blood flow and vascular resistance, metabolism of hormones, regulation of immune and inflammatory reactions, and elaboration of factors that influence the growth of other cell types, particularly the SMCs. The term endothelial dysfunction describes several types of potentially reversible changes in endothelial function that occur in response to environmental stimuli. Vascular SMCs not only control dilation and constriction of blood vessels but elaborate growth factors and synthesize collagen, elastin, and other components of the ECM that are important in both normal vascular repair and pathologic processes such as atherosclerosis.

**DISORDERS OF THE ARTERIAL CIRCULATION**

After completing this section of the chapter, you should be able to meet the following objectives:

- Describe possible mechanisms involved in the development of atherosclerosis.
- Describe the pathology associated with the vasculitides and relate it to four disease conditions associated with vasculitis.
- Distinguish between the pathology and manifestations of aortic aneurysms and dissection of the aorta.

The arterial system distributes blood to all the tissues in the body. There are three types of arteries—large elastic arteries, including the aorta and its distal branches; medium-sized arteries, such as the coronary and renal arteries; and small arteries and arterioles that pass through the tissues. The large arteries function mainly in transport of blood. The medium-sized arteries are composed predominantly of circular and spirally arranged SMCs. Distribution of blood flow to the various organs and tissues of the body is controlled by contraction and relaxation of the smooth muscle of these vessels. The small arteries and arterioles regulate capillary blood flow. Each of these different types of arteries tends to be affected by different disease processes.

Disease of the arterial system affects body function by impairing blood flow. The effect of impaired blood flow on the body depends on the structures involved and the extent of altered flow. The term ischemia denotes a reduction in arterial flow to a level that is insufficient to meet the oxygen demands of the tissues. Infarction refers to an area of ischemic necrosis in an organ produced by occlusion of its arterial blood supply or its venous drainage. The discussion in this section focuses on blood lipids and hypercholesterolemia, atherosclerosis, vasculitis, arterial disease of the extremities, and arterial aneurysms.

**Hyperlipidemia**

Hyperlipidemia is an excess of lipids in the blood. Lipids are classified as triglycerides or neutral fat, phospholipids, and cholesterol. They are a diverse group of compounds that have many key biological functions. Triglycerides, which are used in energy metabolism, are combinations of three fatty acids condensed with a single glycerol molecule. Phospholipids, which contain a phosphate group, are important structural constituents of lipoproteins, blood clotting components, the myelin sheath, and cell membranes. Although cholesterol is not composed of fatty acids, its steroid nucleus is synthesized from fatty acids, and thus, its chemical and physical activity is similar to that of other lipid substances.

Elevated levels of blood cholesterol (hypercholesterolemia) are implicated in the development of atherosclerosis with its attendant risk of heart attack and stroke. This is a major public health issue that is underscored by statistics released by the American Heart Association (AHA). An estimated 102.2 million Americans have a serum cholesterol of greater than 200 mg/dL, and 37.7 million Americans have high-risk serum cholesterol levels (240 mg/dL or greater) that could contribute to a heart attack, stroke, or other cardiovascular event associated with atherosclerosis.
There are four major classes of apoproteins: A (i.e., apoA-I, apoA-II, and apoA-IV), B (i.e., apoB-48, apoB-100), C (i.e., apoC-I, apoC-II, and apoC-III), and apoE. The apo-proteins control the interactions and ultimate metabolic fate of the lipoproteins. Some of the apoproteins activate the lipolytic enzymes that facilitate the removal of lipids from the lipoproteins. Others serve as a reactive site that cellular receptors can recognize and use in the endocytosis and metabolism of the lipoproteins. The major apoprotein in LDL is apoB-100, whereas in HDL it is apoA-I. Research findings suggest that genetic defects in the apoproteins may be involved in hyperlipidemia and accelerated atherosclerosis.

There are two sites of lipoprotein synthesis—the small intestine and the liver. The chylomicrons, which are the largest of the lipoprotein molecules, are synthesized in the wall of the small intestine. They are involved in the transport of dietary (exogenous pathway) triglycerides and cholesterol that have been absorbed from the gastrointestinal tract. Chylomicrons transfer their triglycerides to the cells of adipose and skeletal muscle tissue. Cholesterol remains in the remnant chylomicron particles after the triglycerides are removed. Ultimately the residual cholesterol is then taken up by the liver, which synthesizes it for the development of VLDL and/or excretes it in bile.

The liver synthesizes and releases VLDL and HDL. The VLDLs contain large amounts of triglycerides and lesser amounts of cholesterol esters. They provide the primary pathway for transport of the endogenous triglycerides produced in the liver, as opposed to those obtained from the diet. They are also the body’s main source of energy during prolonged fasting. Like chylomicrons, VLDLs carry their triglycerides to fat and muscle cells, where the triglycerides are removed. The resulting IDL fragments are reduced in triglyceride content and enriched in cholesterol. They are taken to the liver and recycled to form VLDL, or converted to LDL in the vascular compartment. IDLs are the main source of LDL (Fig. 30.5).

LDL, sometimes called the "bad cholesterol," is the main carrier of cholesterol. LDL is removed from the circulation by

**Classification of Lipoproteins**

Because cholesterol and triglyceride are insoluble in plasma, they are encapsulated by a stabilizing coat of water-soluble phospholipids and proteins (called apoproteins). These particles, which are called lipoproteins, transport cholesterol and triglyceride to various tissues for energy utilization, lipid deposition, steroid hormone production, and bile acid formation. There are five types of lipoproteins, classified according to their densities as measured by ultracentrifugation: chylomicrons, very–low-density lipoprotein (VLDL), intermediate-density lipoprotein (IDL), low-density lipoprotein (LDL), and high-density lipoprotein (HDL). Chylomicrons are apparent in the blood about 1 hour after a meal and carry primarily triglycerides but also a small amount of phospholipids, cholesterol, and apoprotein B. VLDL carries large amounts of triglycerides that have a lower density than cholesterol. LDL is the main carrier of cholesterol, whereas HDL actually is 50% protein (Fig. 30.3).

Each type of lipoprotein consists of a large molecular complex of lipids combined with apoproteins. The major lipid constituents are cholesterol esters, triglycerides, nonesterified (or free) cholesterol, and phospholipids. The insoluble cholesterol esters and triglycerides are located in the hydrophobic core of the lipoprotein macromolecule, surrounded by the soluble phospholipids, nonesterified cholesterol, and apoproteins (Fig. 30.4). Nonesterified cholesterol and phospholipids provide a negative charge that allows the lipoprotein to be soluble in plasma.

**FIGURE 30.3** Lipoproteins are named based on their protein content, which is measured in density. Because fats are less dense than proteins, as the proportion of triglycerides decreases, the density increases.
either LDL receptors or by scavenger cells such as monocytes or macrophages. Approximately 70% of LDL is removed through the LDL receptor–dependent pathway, and the rest is removed by the scavenger pathway. Although LDL receptors are widely distributed, approximately 75% are located on hepatocytes. Thus, the liver plays an extremely important role in LDL metabolism. LDL receptor–mediated removal involves binding of LDL to cell surface receptors, followed by endocytosis, a phagocytic process in which LDL is engulfed and moved into the cell in the form of a membrane-covered endocytic vesicle. Within the cell, the endocytic vesicles fuse with lysosomes, and the LDL molecule is enzymatically degraded, causing free cholesterol to be released into the cytoplasm.

Other, nonhepatic tissues (i.e., adrenal glands, SMCs, endothelial cells, and lymphoid cells) also use the LDL receptor–dependent pathway to obtain cholesterol needed for membrane and hormone synthesis. These tissues can control their cholesterol intake by adding or removing LDL receptors. The scavenger pathway involves ingestion by phagocytic monocytes and macrophages. These scavenger cells have receptors that bind LDL that has been oxidized or chemically modified. The amount of LDL that is removed by the scavenger pathway is directly related to the plasma cholesterol level. When there is a decrease in LDL receptors or when LDL levels exceed receptor availability, the amount of LDL that is removed by scavenger cells is greatly increased. The uptake of LDL by macrophages in the arterial wall can result in the accumulation of insoluble cholesterol esters, the formation of foam cells, and the development of atherosclerosis.

HDL is synthesized in the liver and often is referred to as the good cholesterol. HDL participates in the reverse transport of cholesterol by carrying cholesterol from the peripheral tissues back to the liver. Epidemiologic studies have shown an inverse relation between HDL levels and the development of atherosclerosis. It is thought that HDL, which is low in cholesterol and rich in surface phospholipids, facilitates the clearance of cholesterol from the periphery (including atheromatous plaques) and transports it to the liver, where it may be excreted rather than reused in the formation of VLDL (reverse cholesterol transport). The mechanism whereby HDL promotes the movement of cholesterol from peripheral cells to lipid-poor HDL involves a specialized
lipid transporter called the ATP-binding cassette transporters (ABCA1 and ABCG1). These transporters play a pivotal role in the anti-inflammatory effects of HDL. Defects in this system (resulting from mutations in the ABCA1 transporter) are responsible for Tangier disease, which is characterized by accelerated atherosclerosis and little or no HDL. HDL is also believed to inhibit cellular uptake of LDL by reducing oxidation, thereby preventing uptake of oxidized LDL by the scavenger receptors on macrophages. It has been observed that regular exercise, moderate alcohol consumption, and certain lipid medications increase HDL levels, while smoking and the metabolic syndrome are associated with decreased levels of HDL.

Etiology and Pathogenesis of Hyperlipidemia

Serum cholesterol levels may be elevated as a result of an increase in any of the lipoproteins—the chylomicrons, VLDL, IDL, LDL, or HDL. The commonly used classification system for hyperlipidemia is based on the type of lipoprotein involved. Several factors, including nutrition, genetics, medications, comorbid conditions, and metabolic diseases, can raise blood lipid levels. Most cases of elevated levels of cholesterol are probably multifactorial. Some people may have increased sensitivity to dietary cholesterol, others have a lack of LDL receptors, and still others have an altered synthesis of the apoproteins, including oversynthesis of apoB-100, the major apoprotein in LDL.

Hypercholesterolemia (hyperlipoproteinemia) can be classified as either primary or secondary hypercholesterolemia. Primary hypercholesterolemia describes elevated cholesterol levels that develop independent of other health problems or lifestyle behaviors, whereas secondary hypercholesterolemia is associated with other health problems and behaviors.

Many types of primary hypercholesterolemia have a genetic basis. There may be a defective synthesis of the apoproteins, a lack of receptors, defective receptors, or defects in the handling of cholesterol in the cell that are genetically determined. For example, the LDL receptor is deficient or defective in the genetic disorder known as familial hypercholesterolemia (type 2A). This autosomal dominant type of hyperlipoproteinemia results from a mutation in the gene specifying the receptor for LDL. Because most of the circulating cholesterol is removed by receptor-dependent mechanisms, blood cholesterol levels are markedly elevated in people with this disorder. The disorder is probably one of the most common of all mendelian disorders. Plasma LDL levels in people with the heterozygote form of the disease range between 250 and 500 mg/dL. However, in people with the homozygote form of the disease, LDL cholesterol levels may rise to 1000 mg/dL. Although people with the heterozygote form of the disease commonly have an elevated cholesterol level from birth, they do not develop symptoms until adult life, when they often develop xanthomas (i.e., cholesterol deposits) along the tendons, and atherosclerosis appears (Fig. 30.6). Myocardial infarction is seen in this population, but at a later age (40 to 45 years of age in men) compared to those with the homozygote form of the disease. Those with the homozygote form are much more severely affected; they have cutaneous xanthomas in childhood and may experience myocardial infarction early.

Causes of secondary hyperlipoproteinemia include obesity with high-calorie intake and diabetes mellitus. High-calorie diets increase the production of VLDL, with triglyceride elevation and high conversion of VLDL to LDL. Excess ingestion of cholesterol may reduce the formation of LDL receptors and thereby decrease LDL removal. Diets that are high in triglycerides and saturated fats increase cholesterol synthesis and suppress LDL receptor activity.

In diabetes mellitus and the metabolic syndrome, typical dyslipidemia is seen with elevation of triglycerides, low HDL, and minimal or modest elevation of LDL. Other systemic disorders that can elevate lipids include hypothyroidism,
nephrotic syndrome, and obstructive liver disease. Medications such as beta-blockers, estrogens, and protease inhibitors (used in the treatment of human immunodeficiency virus [HIV] infection) can also increase lipid levels.

**Diagnosis of Hyperlipidemia**

The Third Report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults includes a classification system for hyperlipidemia that describes optimal to very high levels of LDL cholesterol, desirable to high levels of total cholesterol, and low and high levels of HDL cholesterol. The NCEP recommends that all adults 20 years of age and older should have a fasting lipoprotein profile (total cholesterol, LDL cholesterol, HDL cholesterol, and triglycerides) measured once every 5 years. Normal ranges can be found at the NCEP website at http://old.nhlbi.nih.gov/cholesterol/index.htm. If testing is done in the nonfasting state, only the total cholesterol and HDL are considered useful. A follow-up lipoprotein profile should be done on people with nonfasting total cholesterol levels of 200 mg/dL or more or HDL levels lower than 40 mg/dL. Lipoprotein measurements are particularly important in people at high risk for developing coronary heart disease (CHD) since there are few if any early clinical manifestations of hyperlipidemia.

**Treatment of Hyperlipidemia**

The NCEP continues to identify reduction in LDL cholesterol as the primary target for cholesterol-lowering therapy, particularly in people at risk for CHD. The major risk factors for CHD, exclusive of LDL cholesterol levels, that modify LDL cholesterol goals include cigarette smoking, hypertension, family history of premature CHD in a first-degree relative, age (men ≥45 years; women ≥55 years), and an HDL cholesterol level less than 40 mg/dL. Accordingly, the NCEP has updated the 2001 guidelines for management of LDL cholesterol based on risk factors. The updated guidelines recommend that persons with zero or no major risk factors should have an LDL cholesterol goal of 160 mg/dL or less; those with two or more of the major risk factors should have an LDL cholesterol goal of less than 130 mg/dL; people with high-risk factors (i.e., those with CHD, other forms of atherosclerotic disease, or diabetes) should have an LDL cholesterol goal of less than 100 mg/dL; and persons with very high-risk factors (i.e., acute coronary syndromes or CHD with other risk factors) should have an LDL cholesterol of less than 70 mg/dL. The guidelines also recommend that people with a greater than 20% 10-year risk of experiencing myocardial infarction or coronary death, as determined by the risk assessment tool developed from Framingham Heart Study data, should have an LDL cholesterol goal of less than 100 mg/dL. (To calculate a risk score, see www.nhlbi.nih.gov/guidelines/cholesterol.)

The management of hypercholesterolemia focuses on dietary and therapeutic lifestyle changes; when these are unsuccessful, pharmacologic treatment may be necessary. Therapeutic lifestyle changes include an increased emphasis on physical activity, dietary measures to reduce LDL cholesterol levels, smoking cessation, and weight reduction for people who are overweight.

Several dietary elements affect cholesterol and its lipoprotein fractions: (1) excess calorie intake, (2) saturated and trans fats, and (3) cholesterol. Excess calories consistently lower HDL and less consistently elevate LDL. Saturated fats in the diet can strongly influence cholesterol levels. Each 1% of saturated fat relative to caloric intake increases the cholesterol level by an average of 2.8 mg/dL. Depending on individual differences, it raises the VLDL and the LDL. Trans fats, which are manufactured from vegetable oils and are used to enhance the taste and extend the shelf life of fast foods, are more atherogenic than saturated fats. Dietary cholesterol tends to increase LDL cholesterol. On average, each 100 mg of ingested cholesterol raises the serum cholesterol 8 to 10 mg/dL.

The aim of dietary therapy is to reduce total and LDL cholesterol levels and increase HDL cholesterol by reduction in total calories and to reduce the percentage of total calories from saturated fat and cholesterol. The AHA has issued new dietary guidelines that focus on an overall plan of healthy food choices and increased physical activity to decrease the risk for development of cardiovascular disease (CVD). The specific guidelines are intended to assist the general public in the maintenance of a body mass index lower than 25 (weight in kilograms divided by body surface area in square meters), to achieve and maintain a low total cholesterol and LDL and a high HDL, and to maintain a blood pressure within normal limits. In general, the dietary guidelines emphasize an increased intake of fruits, vegetables, and fish and a decreased intake of fat, cholesterol, sugars, alcohol, and salt. For people who already have an elevated LDL, the AHA recommends that saturated fat be restricted to less than 7% of the total daily intake, trans fat to less than 1% of the total daily intake, and cholesterol to less than 300 mg/day. However, even with strict adherence to the diet, drug therapy is usually necessary. Clinical data suggest that drug therapy may be efficacious even for those with normal LDL cholesterol since some of the cardioprotective effects of the statin drugs are not just related to LDL lowering, but to their anti-inflammatory effects.

Lipid-lowering drugs work in several ways, including decreasing cholesterol production, decreasing cholesterol absorption from the intestine, and removing cholesterol from the bloodstream. Drugs that act directly to decrease cholesterol levels also have the beneficial effect of further lowering cholesterol levels by stimulating the production of additional LDL receptors. Unless lipid levels are severely elevated, it is recommended that a minimum of 3 months of intensive diet therapy be undertaken before drug therapy is considered. However, certain high-risk groups (e.g., people with diabetes who are at increased cardiovascular risk) are now started on statin therapy at the same time as therapeutic lifestyle changes are initiated.

There currently are five major types of medications available for treating hypercholesterolemia: HMG CoA reductase inhibitors (statins), bile acid–binding resins, cholesterol absorption inhibitor agents, niacin, and the fibrates.
Inhibitors of HMG CoA reductase (e.g., atorvastatin, rosvastatin, simvastatin), a key enzyme in the cholesterol biosynthetic pathway, can reduce or block the hepatic synthesis of cholesterol and are the cornerstone of LDL-reducing therapy. Statins also reduce triglyceride levels and increase HDL levels. Statin therapy has been shown to reduce the risk for acute coronary syndromes and stroke in secondary prevention.12

The bile acid–binding resins (e.g., cholestyramine, colestipol, colesevalam) bind and sequester cholesterol-containing bile acids in the intestine. This leads to increased production of LDL receptors by the liver, with resulting increased removal of cholesterol from the blood for synthesis of new bile acids. These agents are typically used as adjuncts to statin therapy for patients requiring further reductions in LDL and a 3% to 5% increase in HDL cholesterol.

Nicotinic acid, a niacin congener, blocks the synthesis and release of VLDL by the liver, thereby lowering not only VLDL levels but also IDL and LDL levels. Nicotinic acid also increases HDL concentrations up to 15% to 35%.12 The fibrates (e.g., fenofibrate and gemfibrozil) also decrease the synthesis of VLDL by the liver, but also enhance the clearance of triglycerides from the circulation resulting in a triglyceride decrease of 20% to 50%.

Atherosclerosis

Atherosclerosis is a type of arteriosclerosis or hardening of the arteries. The term *atherosclerosis*, which comes from the Greek words *atheros* (“gruel” or “paste”) and *sclerosis* (“hardness”), denotes the formation of fibrofatty lesions in the intimal lining of the large- and medium-sized arteries such as the aorta and its branches, the coronary arteries, and the large vessels that supply the brain (Fig. 30.7).

Although there has been a gradual decline in deaths from atherosclerosis over the past several decades, one complication of atherosclerosis, CVD, remains the leading cause of death among men and women in the United States.3 The reported decline in death rate probably reflects new and improved methods of medical treatment and improved health care practices resulting from an increased public awareness of the factors that predispose to the development of this disorder. In 2011, the major complications of atherosclerosis, including ischemic heart disease, stroke, and peripheral vascular disease, accounted for approximately 33.6% of the deaths in the United States.17

Atherosclerosis begins as an insidious process, and clinical manifestations of the disease typically do not become evident for 20 to 40 years or longer. Fibrous plaques commonly begin to appear in the arteries of Americans in their third decade.

**Etiology and Risk Factors**

The major risk factor for atherosclerosis is hypercholesterolemia, which can be modified. Other risk factors, such as increasing age, family history of premature CHD, and male sex, cannot be changed. The tendency toward the development of atherosclerosis appears to run in families. People who come from families with a strong history of heart disease or stroke due to atherosclerosis are at greater risk for developing atherosclerosis than those with a negative family history. Several genetically determined alterations in lipoprotein and cholesterol metabolism have been identified, and it seems likely that others will be identified in the future.5 The incidence of atherosclerosis increases with age. Other factors being equal, men are at greater risk for development of CVD than are premenopausal women, probably because of the protective effects of natural estrogens. After menopause, the incidence of atherosclerosis-related diseases in women increases, and the frequency of myocardial infarction in the two sexes tends to equalize.3

The major risk factors for atherosclerosis that can be affected by a change in health care behaviors include high blood cholesterol levels (specifically high LDL cholesterol levels), cigarette smoking, obesity and visceral fat, hypertension, and diabetes mellitus (traditional cardiovascular risk factors). Cigarette smoking is closely linked with CVD and sudden death. Endothelial damage may be worsened by cigarette smoke. Prolonged smoking of years of one pack or more per day doubles the damage to the endothelium. However, stopping smoking reduces the risk of endothelial damage significantly.3

Hypertension or high blood pressure increases the risk of atherosclerotic coronary artery disease by twofold. Type 2 diabetes mellitus increases the risk for disease greater then twofold. When a person has hypertension and type 2 diabetes, his or her risk for atherosclerotic coronary artery disease increases by eightfold.1

However, not all atherothrombotic vascular disease can be explained by the established genetic and environmental risk factors. Other, so-called nontraditional, cardiovascular risk factors can be associated with an increased risk for development of atherosclerosis, including C-reactive protein (CRP), serum homocysteine, serum lipoprotein(a), and infectious agents.5,11

Considerable interest in the role of inflammation in the etiology of atherosclerosis has emerged over the last few years.10,17,18 In particular, CRP is now considered a major risk factor marker.19,20 CRP is a serum marker for systemic inflammation (see Chapter 14). Several prospective studies have indicated that elevated CRP levels are associated with vascular disease. The pathophysiologic role of CRP in atherosclerosis has not yet been defined. High-sensitivity CRP (hs-CRP) may be a better predictor of cardiovascular risk than lipid measurement alone.20 Furthermore, greater than 75% of cardiovascular events occur in women with a normal LDL (<160mg/dL).3 In the Heart Protection Study, statin therapy decreased cardiovascular complications even in people with a normal LDL. This was thought to be due to the anti-inflammatory effects of these agents. Inflammation (as assessed by a decrease in hs-CRP) can be reduced by using certain lifestyle changes (exercise and reducing stress) and by drugs (including statins, fibrates, and thiazolidinediones). Serum hs-CRP levels of less than 1, 1 to 3, and over 3 mg/L correspond, respectively, to low-, moderate-, and high-risk groups for future cardiovascular events.20 In most clinical settings, a single hs-CRP assessment is likely to be adequate as long as levels less than 10 mg/L are observed. Because CRP is an acute inflammatory phase reactant, major infections, trauma, or acute hospitalization can elevate CRP levels (usually 100-fold or more). Thus, CRP levels to determine cardiovascular risk should be performed when the person is clinically stable. If the level remains markedly elevated, an alternative source of systemic inflammation should be considered.20

Homocysteine is derived from the metabolism of dietary methionine, an amino acid that is abundant in animal protein. The normal metabolism of homocysteine requires adequate levels of folate, vitamin B6, and riboflavin. Homocysteine inhibits elements of the anticoagulant cascade and is associated with endothelial damage, which is thought to be an important first step in the development of atherosclerosis.15 However, supplementation with folic acid, vitamin B6, and vitamin B12, to decrease plasma homocysteine levels is not generally recommended for either primary or secondary prevention of CVD based on recent clinical evidence.

Lipoprotein(a) is similar to LDL in composition and is an independent risk factor for the development of premature CHD. Lipoprotein(a) and can cause atherosclerosis by binding to macrophages through a high-affinity receptor that promotes foam cell formation and the deposition of cholesterol in atherosclerotic plaques. Lipoprotein(a) levels should be determined in people who have premature coronary artery disease or a positive family history since they are not altered by traditional cholesterol-lowering drugs.18 Lipoprotein levels have been shown to be reduced with the use of nicotinic therapy.5 The desirable level is less than 14 mg/dL.

There also has been increased interest in the possible connection between infectious agents (e.g., Chlamydia pneumoniae, herpesvirus, cytomegalovirus) and the development of vascular disease. The presence of these organisms in atherosclerotic lesions has been demonstrated by immunocytochemistry, but no cause-and-effect relationship has been established. The organisms may play a role in atherosclerotic development by initiating and enhancing the inflammatory response.2

Pathogenesis
The lesions associated with atherosclerosis are of three types—the fatty streak, the fibrous atheromatous plaque, and the complicated lesion. The latter two are responsible for the clinically significant manifestations of the disease.

Fatty streaks are thin, flat, yellow intimal discolorations that progressively enlarge by becoming thicker and slightly elevated as they grow in length. Histologically, they consist of macrophages and SMCs that have become distended with lipid to form foam cells. Fatty streaks are present in children, often in the first year of life.13 This occurs regardless of geographic setting, sex, or race. They increase in number until about 20 years of age, and then they remain static or regress. Damage to the endothelium is an early marker that can later become atherosclerotic. Once the endothelium is damaged circulating monocytes and lipids begin to adhere to the area. This fibrous atheromatous plaque is characterized by the gray to pearly white appearance due to the macrophages that ingest and oxidize accumulated lipoproteins and form a visible fatty streak. Over time the fatty streaks grow larger and proliferate into the smooth muscle. As the lesions increase in size, they encroach on the lumen of the artery. The macrophages release substances that cause inflammation and eventually may occlude the vessel or predispose to thrombus formation, causing a reduction of blood flow (Fig. 30.8).2 Because blood flow is related to the fourth power of the vessel radius, the reduction in blood flow becomes increasingly greater as the disease progresses.
blood cells, particularly the monocytes (blood macrophages), normally occur throughout life; these interactions increase when blood cholesterol levels are elevated. One of the earliest responses to elevated cholesterol levels is the attachment of monocytes to the endothelium. The monocytes have been observed to emigrate through the cell-to-cell attachments of the endothelial layer into the subendothelial spaces, where they are transformed into macrophages. Activated macrophages release free radicals that oxidize LDL. Oxidized LDL is toxic to the endothelium, causing endothelial loss and exposure of the subendothelial tissue to blood components. This leads to platelet adhesion and aggregation and fibrin deposition. Platelets and activated macrophages release various factors that are thought to promote growth factors that modulate the proliferation of SMCs and deposition of ECM in the lesions. Activated macrophages also ingest oxidized LDL (by uptake through the scavenger receptor) to become foam cells, which are present in all stages of atherosclerotic plaque formation. Lipids released from necrotic foam cells accumulate to form the lipid core of unstable plaques. Unstable plaques typically are characterized histologically by a large central lipid core, inflammatory infiltrate, and a thin fibrous cap. These “vulnerable plaques” are at risk of rupture (plaque rupture), often at the shoulder of the plaque (see Fig. 30.8A) where the fibrous cap is thinnest (because of the presence of local inflammatory cells and mediators that degrade the cap) and the mechanical stresses highest.
Understanding The Development of Atherosclerosis

Atherosclerosis is characterized by the development of atheromatous lesions within the intimal lining of the large and medium-sized arteries that protrude into and can eventually obstruct blood flow. The development of atherosclerotic lesions is a progressive process involving (1) endothelial cell injury, (2) migration of inflammatory cells, (3) SMC proliferation and lipid deposition, and (4) gradual development of the atheromatous plaque with a lipid core.

Endothelial Cell Injury

The vascular endothelium consists of a single layer of cells with cell-to-cell attachments, which normally protects the subendothelial layers from interacting with blood cells and other blood components. Agents such as smoking, elevated LDL levels, immune mechanisms, and mechanical stress associated with hypertension share the potential for causing endothelial injury with adhesion of monocytes and platelets.

Migration of Inflammatory Cells

Early in the development of atherosclerotic lesions, endothelial cells begin to express selective adhesion molecules that bind monocytes and other inflammatory cells that initiate the atherosclerotic lesions. After monocytes adhere to the endothelium, they migrate between the endothelial cells to localize in the intima, transform into macrophages, and engulf lipoproteins, largely LDL.
Lipid Accumulation and Smooth Muscle Cell Proliferation

Although the recruitment of monocytes, their differentiation into macrophages and subsequent ingestion of lipids, and their ultimate transformation into foam cells is protective in that it removes excess lipids from the circulation, progressive accumulation eventually leads to lesion progression. Activated macrophages release toxic oxygen species that oxidize LDL; they then ingest the oxidized LDL to become foam cells. They also produce growth factors that contribute to the migration and proliferation of SMCs and the elaboration of ECM.

Plaque Structure

Atherosclerotic plaques consist of an aggregation of SMCs, macrophages, and other leukocytes; ECM, including collagen and elastic fibers; and intracellular and extracellular lipids. Typically, the superficial fibrous cap is composed of SMCs and dense ECM. Immediately beneath and to the side of the fibrous cap is a cellular area (the shoulder) consisting of macrophages, SMCs, and lymphocytes. Below the fibrous cap is a central core of lipid-laden foam cells and fatty debris. Rupture, ulceration, or erosion of an unstable or vulnerable fibrous cap may lead to hemorrhage into the plaque or thrombotic occlusion of the vessel lumen.

Clinical Manifestations

Atherosclerosis begins as an insidious process, and clinical manifestations of the disease typically do not become evident for 20 to 40 years or longer. Fibrous plaques commonly begin to appear in the arteries of Americans in their third decade. The clinical manifestations of atherosclerosis depend on the vessels involved and the extent of vessel obstruction.

Atherosclerotic plaques (lesions) produce their effects through

- Narrowing of the vessel and production of ischemia
- Sudden vessel obstruction due to plaque hemorrhage or rupture
- Thrombosis and formation of emboli resulting from damage to the vessel endothelium
- Aneurysm formation due to weakening of the vessel wall

In larger vessels, such as the aorta, the important complications are those of thrombus formation and weakening of the vessel wall. In medium-sized arteries, such as the coronary and cerebral arteries, ischemia and infarction due to vessel occlusion are more common. Although atherosclerosis can affect any organ or tissue, the arteries supplying the heart, brain, kidneys, lower extremities, and small intestine are most frequently involved.
Vasculitis

The vasculitides are a group of vascular disorders that cause inflammatory injury and necrosis of the blood vessel wall (i.e., vasculitis). The vasculitides, which are a common pathway for tissue and organ involvement in many different disease conditions, involve the endothelial cells and SMCs of the vessel wall. Vessels of any type (arteries, veins, and capillaries) in virtually any organ can be affected. Because they may affect veins and capillaries, the terms vasculitis, angiitis, and arteritis are often used interchangeably. Clinical manifestations often include fever, myalgia, arthralgia, and malaise. Vasculitis may result from direct injury to the vessel, infectious agents, or immune processes, or they may be secondary to other disease states such as systemic lupus erythematosus. Physical agents such as cold (i.e., frostbite), irradiation (i.e., sunburn), mechanical injury, immune mechanisms, and toxins may secondarily cause vessel damage, often leading to necrosis of the vessels. Small vessel vasculitides are sometimes associated with antineutrophil cytoplasmic antibodies (ANCA). ANCA are antibodies directed against certain proteins in the cytoplasm of neutrophils. These autoantibodies may cause endothelial damage. Serum ANCA titers, which can correlate with disease activity, may serve as a useful quantitative diagnostic marker for these disorders.

The vasculitides are commonly classified based on etiology, pathologic findings, and prognosis. One classification system divides the conditions into three groups: (1) small vessel, (2) medium-sized vessel, and (3) large vessel vasculitides (Table 30.2). Small vessel refers to small arteries (ANCA-associated disease only), arterioles, venules, and capillaries; medium vessels refer to medium- and small-sized arteries and arterioles; and large vessel refers to the aorta and its major tributaries. The small vessel vasculitides are involved in a number of different diseases, most of which are mediated by type III immune complex hypersensitivity reaction. They commonly involve the skin and are often a complication of an underlying disease (i.e., vasculitis associated with neoplasms or connective tissue disease) and exposure to environmental agents (i.e., serum sickness and urticarial vasculitis). ANCA-positive small vessel vasculitis includes microscopic polyangiitis, Wegener granulomatosis, and the Churg-Strauss syndrome. These ANCA-positive vasculitides are treated by similar regimens.

Medium-sized vessel vasculitides produce necrotizing damage to medium-sized muscular arteries of major organ systems. This group includes polyarteritis nodosa, Kawasaki disease, and thromboangiitis obliterans. Large vessel vasculitides involve large elastic arteries. They include giant cell (temporal) arteritis, polymyalgia rheumatica, and Takayasu arteritis. The following discussion focuses on two of the vasculitides: polyarteritis nodosa and giant cell (temporal) arteritis.

**Polyarteritis Nodosa**

*Polyarteritis nodosa*, so named because of the numerous nodules found along the course of muscular arteries, is a primary multisystem inflammatory disease of smaller and medium-sized
blood vessels, especially those of the kidney, liver, intestine, peripheral nerve, skin, and muscle. The disease is seen more commonly in men than women.

**Etiology**
The cause of polyarteritis nodosa remains unknown. It can occur in drug abusers and may be associated with the use of certain drugs such as allopurinol and the sulfonamides. There is an association between polyarteritis nodosa and hepatitis B, with 10% to 30% of people with the disease having antibodies to hepatitis B. Other associations include serous otitis media, hairy cell leukemia, and hyposensitization therapy for allergies. People with connective tissue diseases such as systemic lupus erythematosus, rheumatoid arthritis, and primary Sjögren syndrome may have manifestations similar to those of primary polyarteritis nodosa.3–5

**Clinical Manifestations**
The onset of polyarteritis nodosa course can be acute, subacute, or chronic with long periods of symptom-free intervals.3 Clinical signs and symptoms may vary due to the widely varied vascular involvement. It usually begins complaints of anorexia, weight loss, fever, and fatigue often accompanied by signs of organ involvement. The kidney is the most frequently affected organ, and hypertension is a common manifestation of the disorder. Gastrointestinal involvement may manifest as abdominal pain, nausea, vomiting, or diarrhea. Myalgia, arthralgia, and arthritides are common, as are peripheral neuropathies such as paresthesias, pain, and weakness. Central nervous system complications include thrombotic and hemorrhagic stroke. Cardiac manifestations result from involvement of the coronary arteries. Skin lesions also may occur and are highly variable. They include reddish blue, mottled areas of discoloration of the skin of the extremities called livedo reticularis, purpura (i.e., black and blue discoloration from bleeding into the skin), urticaria (i.e., hives), and ulcers.

**Diagnosis and Treatment**
Laboratory findings, although variable, include an elevated erythrocyte sedimentation rate, leukocytosis, anemia, and signs of organ involvement such as hematuria and abnormal liver function test results. The diagnosis is confirmed through biopsy specimens demonstrating necrotizing vasculitis of the small and large arteries. Treatment involves use of high-dose corticosteroid therapy and often-cytotoxic immunosuppressant agents (e.g., azathioprine, cyclophosphamide). Typically, 3 months of a cytotoxic immunosuppressant is given, followed by tapered glucocorticoids over the next 4 months.22 Before the availability of corticosteroids and immunosuppressive agents, the disease commonly was fatal. For people with polyarteritis nodosa associated with hepatitis B, aggressive simultaneous treatment of the hepatitis with antiviral agents is indicated.

**Giant Cell Temporal Arteritis**
Temporal arteritis (i.e., giant cell arteritis), the most common of the vasculitides, is a focal inflammatory condition of medium-sized and large arteries. It predominantly affects branches of arteries originating from the aortic arch, including the superficial temporal, vertebral, ophthalmic, and posterior ciliary arteries. The disorder progresses to involve the entire artery wall with focal necrosis and granulomatous inflammation involving multinucleated giant cells (Fig. 30.9). It is more common in older adults, with a 2:1 female-to-male ratio. The cause is unknown. However, an autoimmune origin, such as an initial T cell–mediated immune response, has been suggested.3

The disorder often is insidious in onset and may be heralded by the sudden onset of headache, tenderness over the artery, swelling and redness of the overlying skin, blurred vision or diplopia, and facial pain. Almost one half of affected persons have systemic involvement in the form of polymyalgia rheumatica. Up to 10% of people with giant cell arteritis go on to develop aortic aneurysm (especially thoracic).

Diagnosis is based on the clinical manifestations, a characteristically elevated erythrocyte sedimentation rate and CRP, and temporal artery biopsy. Treatment includes use of high-dose corticosteroids without delay because of the significant risk of visual symptoms. Before people with the disorder were treated with corticosteroids, blindness developed in almost 80% of cases due to involvement of the posterior ciliary artery. A typical starting dose of prednisolone is 40 to 60 mg/day for 4 weeks.22–23

**Arterial Disease of the Extremities**
Disorders of the circulation in the extremities often are referred to as peripheral vascular disorders. In many respects, the disorders that affect arteries in the extremities are the same as those affecting the coronary and cerebral arteries in that they produce ischemia, pain, impaired function, and in some cases infarction and tissue necrosis. Not only are the effects similar, but the pathologic conditions that impair circulation in the extremities are identical. This section focuses on acute arterial occlusion of the extremities, atherosclerotic occlusive disease, thromboangiitis obliterans, and Raynaud disease and phenomenon.
Acute Arterial Occlusion

Acute arterial occlusion is a sudden event that interrupts arterial flow to the affected tissues or organ. Most acute arterial occlusions are the result of an embolus or a thrombus. Although much less common than emboli and thrombi, trauma or arterial spasm caused by arterial cannulation can be another cause of acute arterial occlusion.

Etiology and Pathogenesis

An embolus is a freely moving particle such as a blood clot that breaks loose and travels in the larger vessels of the circulation until lodging in a smaller vessel and occluding blood flow. Most emboli arise in the heart and are caused by conditions that cause blood clots to develop on the wall of a heart chamber or valve surface. Emboli usually are a complication of heart disease: ischemic heart disease with or without infarction, atrial fibrillation, or rheumatic heart disease. Prosthetic heart valves can be another source of emboli. Other types of emboli are fat emboli that originate from bone marrow of fractured bones, air emboli from the lung, and amniotic fluid emboli that develop during childbirth. Acute arterial embolism is associated with a 5% to 25% risk of affected limb loss and a 25% to 30% increase in hospital mortality. Heart disease is responsible for over half these deaths.

A thrombus is a blood clot that forms on the wall of a vessel and continues to grow until reaching a size that obstructs blood flow. Thrombi often arise as the result of erosion or rupture of the fibrous cap of an arteriosclerotic plaque.

Clinical Manifestations

The signs and symptoms of acute arterial occlusion depend on the artery involved and the adequacy of the collateral circulation. Emboli tend to lodge in bifurcations of the major arteries, including the aorta and iliac, femoral, and popliteal arteries. The presentation of acute arterial embolism is often described as that of the seven “Ps”:

- Pistol shot (acute onset)
- Pallor
- Polar (cold)
- Pulselessness
- Pain
- Paresthesia
- Paralysis

Occlusion in an extremity causes sudden onset of acute pain with numbness, tingling, weakness, pallor, and coldness. There often is a sharp line of demarcation between the oxygenated tissue above the line of obstruction and the ischemic tissue below the line of obstruction. Pulses are absent below the level of the occlusion. These changes are followed rapidly by cyanosis, mottling, and loss of sensory, reflex, and motor function. Tissue death occurs unless blood flow is restored.

Diagnosis and Treatment

Diagnosis of acute arterial occlusion is based on signs of impaired blood flow. It uses visual assessment, palpation of pulses, and methods to assess blood flow. Treatment of acute arterial occlusion is aimed at restoring blood flow. An embolectomy, surgical removal of the embolus, is the optimal therapy when a large artery is occluded.

Thrombolytic therapy (i.e., streptokinase or tissue plasminogen activator) may be used in an attempt to dissolve the clot. Anticoagulant therapy (i.e., heparin) usually is given to prevent extension of the embolus and to prevent progression of the original thrombus. Application of cold should be avoided, and the extremity should be protected from injury resulting from hard surfaces and overlying bedclothes.

Atherosclerotic Occlusive Disease

Atherosclerosis is an important cause of peripheral artery disease (PAD) and is seen most commonly in the vessels of the lower extremities. The condition is sometimes referred to as arteriosclerosis obliterans. The superficial femoral and popliteal arteries are the most commonly affected vessels. When lesions develop in the lower leg and foot, the tibial, common peroneal, or pedal vessels are the arteries most commonly affected. The disease is seen most commonly in men and women as they advance in age. Approximately 20% of people in their 70s have PAD.

Etiology

The risk factors for this disorder are similar to those for atherosclerosis. Cigarette smoking contributes to the progression of the atherosclerosis of the lower extremities and to the development of symptoms of ischemia. People with diabetes mellitus develop more extensive and rapidly progressive vascular disease than do people who do not have diabetes.

Clinical Manifestations

As with atherosclerosis in other locations, the signs and symptoms of vessel occlusion are gradual. Usually, there is at least a 50% narrowing of the vessel before symptoms of ischemia arise. The primary symptom of chronic obstructive arterial disease is intermittent claudication or pain with walking. Typically, people with the disorder complain of calf pain because the gastrocnemius muscle has the highest oxygen consumption of any muscle group in the leg during walking. Some people may complain of a vague aching feeling or numbness, rather than pain. Other activities such as swimming, bicycling, and climbing stairs use other muscle groups and may not incite the same degree of discomfort as walking.

Other signs of ischemia include atrophic changes and thinning of the skin and subcutaneous tissues of the lower leg and diminution in the size of the leg muscles. The foot often is cool, and the popliteal and pedal pulses are weak or absent. Limb color blanches with elevation of the leg because of the effects of gravity on perfusion pressure and becomes deep red when the leg is in the dependent position because of an auto-regulatory increase in blood flow and a gravitational increase in perfusion pressure.

When blood flow is reduced to the extent that it no longer meets the minimal needs of resting muscle and nerves, ischemic pain at rest, ulceration, and gangrene develop. As tissue
necrosis develops, there typically is severe pain in the region of skin breakdown, which is worse at night with limb elevation and is improved with standing.\textsuperscript{25}

**Diagnosis**

Diagnostic methods include inspection of the limbs for signs of chronic low-grade ischemia such as subcutaneous atrophy, brittle toenails, hair loss, pallor, coolness, or dependent rubor. Palpation of the femoral, popliteal, posterior tibial, and dorsalis pedis pulses allows for an estimate of the level and degree of obstruction. The ratio of ankle to arm (\textit{i.e.}, tibial and brachial arteries) systolic blood pressure is used to detect significant obstruction, with a ratio of less than 0.9 indicating occlusion. Normally, systolic pressure in the ankle exceeds that in the brachial artery because systolic pressure and pulse pressure tend to increase as the pressure wave moves away from the heart. Blood pressures may be taken at various levels on the leg to determine the level of obstruction. A Doppler ultrasound stethoscope may be used for detecting pulses and measuring blood pressure. Ultrasound imaging, magnetic resonance imaging (MRI) arteriography, spiral computed tomographic (CT) arteriography, and invasive contrast angiography may also be used as diagnostic methods.\textsuperscript{24,25}

**Treatment**

The two goals of treatment in people with PAD are (1) to decrease their considerable cardiovascular risk and (2) to reduce symptoms. People with PAD should be evaluated for coexisting coronary and cerebrovascular atherosclerosis. The risk of death, mainly from coronary and cerebrovascular events, is higher than if they did not have PAD.\textsuperscript{25} It is also important to address other cardiovascular risk factors, including smoking, hypertension, high lipid levels, and diabetes. Smoking cessation should be encouraged, and the coexisting health conditions should be treated appropriately.

Antiplatelet agents (aspirin or clopidogrel) reduce the vascular death rate in people with PAD by about 25\.\textsuperscript{25} Other medications that are useful include statins, cilostazol (a phosphodiesterase inhibitor), and pentoxifylline (an adenosine diphosphate [ADP] receptor antagonist that decreases blood viscosity and improves erythrocyte flexibility). The tissues of extremities affected by atherosclerosis are easily injured and slow to heal. Treatment includes measures directed at protection of the affected tissues and preservation of functional capacity. Walking (slowly) to the point of claudication usually is encouraged because it increases collateral circulation.

Percutaneous or surgical intervention is typically reserved for the person with disabling claudication or limb-threatening ischemia. Surgery (\textit{i.e.}, femoropopliteal bypass grafting using a section of saphenous vein) may be indicated in severe cases. In people with diabetes, the peroneal arteries between the knees and ankles commonly are involved, making revascularization difficult. Thromboendarterectomy with removal of the occluding core of atherosclerotic tissue may be done if the section of diseased vessel is short. Percutaneous transluminal angioplasty and stent placement, in which a balloon catheter is inserted into the area of stenosis and the balloon inflated to increase vessel diameter, is another form of treatment.\textsuperscript{24,25}

**Thromboangiitis Obliterans**

Thromboangiitis obliterans, or Buerger disease, is an inflammatory (\textit{i.e.}, vasculitis) arterial disorder that causes thrombus formation. The disorder affects the medium-sized arteries, usually the plantar and digital vessels in the foot and lower leg. Arteries in the arm and hand also may be affected. It is characterized by segmental, thrombosing, acute and chronic inflammation. Although primarily an arterial disorder, the inflammatory process often extends to involve adjacent veins and nerves. Usually the disease is seen in people less than 35 years of age who are heavy cigarette smokers.

**Etiology and Pathogenesis**

The pathogenesis of Buerger disease remains speculative. However, cigarette smoking and in some instances tobacco chewing seem to be involved. It has been suggested that the nicotine has a direct effect on the endothelial cell toxicity and may trigger an immune response.\textsuperscript{3} Genetic influences are suggested since it is more prevalent in certain ethnic groups.

**Clinical Manifestations**

Pain is the predominant symptom of the disorder. It usually is related to distal arterial ischemia. During the early stages of the disease, there is intermittent claudication in the arch of the foot and the digits. In severe cases, pain is present even when the person is at rest. The impaired circulation increases sensitivity to cold. The peripheral pulses are diminished or absent, and there are changes in the color of the extremity. In moderately advanced cases, the extremity becomes cyanotic when the person assumes a dependent position, and the digits may turn reddish blue even when in a nondependent position. With lack of blood flow, the skin assumes a thin, shiny look and hair growth and skin nutrition suffer. Chronic ischemia causes thick, malformed nails. If the disease continues to progress, tissues eventually ulcerate and gangrenous changes arise that may necessitate amputation.

**Diagnosis and Treatment**

Diagnostic methods are similar to those for atherosclerotic disease of the lower extremities. As part of the treatment program for thromboangiitis obliterans, it is mandatory that the person stop smoking cigarettes or using tobacco. Even passive smoking and nicotine replacement therapy should be eliminated. Other treatment measures are of secondary importance and focus on methods for producing vasodilation and preventing tissue injury. Sympathectomy may be done to alleviate the vasospastic manifestations of the disease.

**Raynaud Disease and Phenomenon**

Raynaud disease or phenomenon is a functional disorder caused by intense vasospasm of the arteries and arterioles in the fingers and, less often, the toes. This is a common disorder affecting 3\% to 5\% of the population and is more common in
women than men. The disorder is divided into two types—the primary type, called Raynaud disease, occurs without demonstrable cause, and the secondary type, called Raynaud phenomenon, is associated with other disease states or known causes of vasospasm.5,26

Etiology and Pathogenesis
Vasospasm implies an excessive vasoconstrictor response to stimuli that normally produce only moderate vasoconstriction. In contrast to other regional circulations that are supplied by vasodilator and vasoconstrictor fibers, the cutaneous vessels of the fingers and toes are innervated only by sympathetic vasoconstrictor fibers. In these vessels, vasodilation occurs by withdrawal of sympathetic stimulation. Cooling of specific body parts such as the head, neck, and trunk produces a sympathetic-mediated reduction in digital blood flow, as does emotional stress.

Raynaud disease is precipitated by exposure to cold or by strong emotions and usually is limited to the fingers. It also follows a more benign course than Raynaud phenomenon, seldom causing tissue necrosis. The cause of vasospasm in primary Raynaud disease is unknown. Raynaud phenomenon is associated with previous vessel injury, such as frostbite, occupational trauma associated with the use of heavy vibrating tools, collagen diseases, neurologic disorders, and chronic arterial occlusive disorders. Another occupation-related cause is the exposure to alternating hot and cold temperatures such as that experienced by butchers and food preparers.26 Raynaud phenomenon often is the first symptom of collagen diseases, such as scleroderma and systemic lupus erythematosus.3

Clinical Manifestations
In Raynaud disease and Raynaud phenomenon, ischemia due to vasospasm causes changes in skin color that progress from pallor to cyanosis, a sensation of cold, and changes in sensory perception, such as numbness and tingling. The color changes usually are first noticed in the tips of the fingers, later moving into one or more of the distal phalanges (Fig. 30.10). After the ischemic episode, there is a period of hyperemia with intense redness, throbbing, and paresthesias. The period of hyperemia is followed by a return to normal color. Although all of the fingers usually are affected symmetrically, in some cases only one or two digits are involved, or only a portion of the digit is affected.

In severe, progressive cases usually associated with Raynaud phenomenon, trophic changes may develop. The nails may become brittle, and the skin over the tips of the affected fingers may thicken. Nutritional impairment of these structures may give rise to arthritis. Ulceration and superficial gangrene of the fingers, although infrequent, may occur.

Diagnosis and Treatment
The initial diagnosis is based on history of vasospastic attacks supported by other evidence of the disorder. Immersion of the hand in cold water may be used to initiate an attack as an aid to diagnosis. Laser Doppler flow velocimetry may be used to quantify digital blood flow during changes in temperature. Raynaud disease is differentiated from Raynaud phenomenon by excluding secondary disorders known to cause vasospasm.26

Treatment measures are directed toward eliminating factors that cause vasospasm and protecting the digits from trauma during an ischemic episode. Abstinence from smoking and protection from cold are priorities. The entire body must be protected from cold, not just the extremities. Avoidance of emotional stress is another important factor in controlling the disorder because anxiety and stress may precipitate a vascular spasm in predisposed people. Vasoconstrictor medications, such as the decongestants contained in allergy and cold preparations, should be avoided. Treatment with vasodilator drugs may be indicated, particularly if episodes are frequent, because frequency encourages the potential for development of thrombosis and gangrene. The calcium channel–blocking drugs (e.g., nifedipine, diltiazem) decrease the severity and frequency of attacks. Prazosin, an α-adrenergic receptor–blocking drug, also may be used. Surgical interruption of sympathetic nerve pathways (sympathectomy) may be used for people with severe symptoms.26

Aneurysms
An aneurysm is an abnormal localized dilation of a blood vessel. Aneurysms can occur in arteries and veins, but they are most common in the aorta. There are two types of aneurysms—true aneurysms and false aneurysms. A true aneurysm is one in which the aneurysm is bounded by a complete vessel wall. The blood in a true aneurysm remains within the vascular compartment. False aneurysm or pseudoaneurysm represents a localized dissection or tear in the inner wall of the artery with formation of an extravascular hematoma that causes vessel enlargement. Unlike true aneurysms, false aneurysms are bounded only by the outer layers of the vessel wall or supporting tissues (Fig. 30.11).

Aneurysms can assume several forms and may be classified according to their cause, location, and anatomic features.

This is because the tension in the wall of a vessel is equal to the pressure multiplied by the radius (i.e., tension = pressure × radius; see Chapter 21). In this case, the pressure in the segment of the vessel affected by the aneurysm does not change but remains the same as that of adjacent portions of the vessel. As an aneurysm increases in diameter, the tension in the wall of the vessel increases in direct proportion to its increased size. If untreated, the aneurysm may rupture because of the increased tension. Even an unruptured aneurysm can cause damage by exerting pressure on adjacent structures and interrupting blood flow.

Aortic Aneurysms

Aortic aneurysms may involve any part of the aorta—the ascending aorta, aortic arch, descending aorta, thoracoabdominal aorta, or abdominal aorta. Multiple aneurysms may be present.

Etiology

The two most common causes of aortic aneurysms are atherosclerosis and degeneration of the vessel media. Half of the people with aortic aneurysms have hypertension. Aortic aneurysms usually develop more frequently in men after the age of 50 years who smoke cigarettes.

Clinical Manifestations

The signs and symptoms of aortic aneurysms depend on the size and location. An aneurysm also may be asymptomatic, with the first evidence of its presence being associated with vessel rupture. Aneurysms of the thoracic aorta are less common than abdominal aortic aneurysms. They account for less than 10% of aortic aneurysms and may present with substernal, back, and neck pain. There also may be dyspnea, stridor, or brassy cough caused by pressure on the trachea. Hoarseness may result from pressure on the recurrent laryngeal nerve, and there may be difficulty swallowing because of pressure on the esophagus. The aneurysm also may compress the superior vena cava, causing distention of neck veins and edema of the face and neck.

Abdominal aortic aneurysms are located most commonly below the level of the renal artery (>90%) and involve the bifurcation of the aorta and proximal end of the common iliac arteries. The infrarenal aorta is normally 2 cm in diameter; an aneurysm is defined as an aortic diameter greater than 3 cm. They can involve any part of the vessel circumference (saccular) or extend to involve the entire circumference (fusiform). Most abdominal aneurysms are asymptomatic. Because an aneurysm is of arterial origin, a pulsating mass may provide the first evidence of the disorder. Typically, aneurysms larger than 4 cm are palpable. The mass may be discovered during a routine physical examination, or the affected person may complain of its presence. Calcification, which frequently exists on the wall of the aneurysm, may be detected during abdominal radiologic examination. Pain may be present and varies from mild mid-abdominal or lumbar
discomfort to severe abdominal and back pain. As the aneurysm expands, it may compress the lumbar nerve roots, causing lower back pain that radiates to the posterior aspects of the legs. The aneurysm may extend to and impinge on the renal, iliac, or mesenteric arteries or to the vertebral arteries that supply the spinal cord. An abdominal aneurysm also may cause erosion of vertebrae. Stasis of blood favors thrombus formation along the wall of the vessel (Fig. 30.12), and peripheral emboli may develop, causing symptomatic arterial insufficiency.

With thoracic and abdominal aneurysms, the most dreaded complication is rupture. The likelihood of rupture correlates with increasing aneurysm size. The risk of rupture rises from less than 2% for small abdominal aneurysms (<4 cm in diameter) to 5% to 10% per year for aneurysms larger than 5 cm in diameter.3

**Diagnosis and Treatment**

Diagnostic methods include use of ultrasonography, echocardiography, CT scans, and MRI. Surgical repair, in which the involved section of the aorta is replaced with a synthetic graft of woven Dacron, frequently is the treatment of choice.27

**Aortic Dissection**

Aortic dissection (dissecting aneurysm) is an acute, life-threatening condition. It involves hemorrhage into the vessel wall with longitudinal tearing of the vessel wall to form a blood-filled channel (Fig. 30.13). Unlike atherosclerotic aneurysms, aortic dissection often occurs without evidence of previous vessel dilation. More than 95% of the cases...
of dissecting aneurysm show transverse tear in the intima and internal media. The dissection can originate anywhere along the length of the aorta. The majority of the dissections involve the ascending aorta. The second most common site is the thoracic aorta just distal to the origin of the subclavian artery.

**Etiology and Pathogenesis**

Aortic dissection is caused by conditions that weaken or cause degenerative changes in the elastic and smooth muscle of the layers of the aorta. It is most common in the 40- to 60-year-old age group and more prevalent in men than in women. Two risk factors predispose to aortic dissection—hypertension and degeneration of the medial layer of the vessel wall. There is a history of hypertension in most cases. Aortic dissection also is associated with connective tissue diseases, such as Marfan syndrome. It also may occur during pregnancy because of changes in the aorta that occur during this time. Other factors that predispose to dissection are congenital defects of the aortic valve (i.e., bicuspid or unicuspid valve structures) and aortic coarctation. Aortic dissection is a potential complication of cardiac surgery or catheterization. Surgically related dissection may occur at the points where the aorta has been incised or cross-clamped. It also has been reported at the site where the saphenous vein was sutured to the aorta during coronary artery bypass surgery.

Aortic dissections are commonly classified into two types, type A and type B, as determined by the level of dissection. The more common (and potentially more serious in terms of complications) proximal lesions, involving the ascending aorta only or both the ascending and the descending aorta, are designated type A. Those not involving the ascending aorta and usually beginning distal to the subclavian artery are designated type B. Aortic dissections are also classified according to time of onset as acute or chronic. Chronic dissections are defined as the persistence of the dissection flap or channel for greater than 2 weeks after initial event. Dissections usually extend distally from the intimal tear. When the ascending aorta is involved, expansion of the wall of the aorta may impair closure of the aortic valve. There also is the risk of aortic rupture with blood moving into the pericardium and compressing the heart. Although the length of dissection varies, it is possible for the abdominal aorta to be involved with progression into the renal, iliac, or femoral arteries. Partial or complete occlusion of the arteries that arise from the aortic arch or the intercostal or lumbar arteries may lead to stroke, ischemic peripheral neuropathy, or impaired blood flow to the spinal cord.

**Clinical Manifestations**

A major symptom of a dissecting aneurysm is the abrupt presence of excruciating pain, described as tearing or ripping. The location of the pain may point to the site of dissection. Pain associated with dissection of the ascending aorta frequently is located in the anterior chest, and pain associated with dissection of the descending aorta often is located in the back. In the early stages, blood pressure typically is moderately or markedly elevated. Later, the blood pressure and the pulse rate become unobtainable in one or both arms as the dissection disrupts arterial flow to the arms. Syncope, hemiplegia, or paralysis of the lower extremities may occur because of occlusion of blood vessels that supply the brain or spinal cord. Heart failure may develop when the aortic valve is involved.

**Diagnosis and Treatment**

Diagnosis of aortic dissection is based on history and physical examination. Aortic angiography, transesophageal echocardiography, CT scans, and MRI studies aid in the diagnosis.

The treatment of dissecting aortic aneurysm may be medical or surgical depending on the type and whether it is acute or chronic. Because aortic dissection is a life-threatening emergency, people with a probable diagnosis are stabilized medically even before the diagnosis is confirmed. Two important factors that participate in propagating the dissection are high blood pressure and the steepness of the pulse wave. Without intervention, these forces continue to cause extension of the dissection. Therefore, medical treatment focuses on control of hypertension and the use of drugs that lessen the force of systolic blood ejection from the heart. Two commonly used drugs, given in combination, are intravenous sodium nitroprusside and a β-adrenergic–blocking drug. Surgical treatment consists of resection of the involved segment of the aorta and replacement with a prosthetic graft. The mortality rate due to untreated dissecting aneurysm is high.

**IN SUMMARY**

The arterial system distributes blood to all the tissues of the body, and lesions of the arterial system exert their effects through ischemia or impaired blood flow. There are two types of arterial disorders: diseases such as atherosclerosis, vasculitis, and peripheral arterial diseases that obstruct blood flow and disorders such as aneurysms that weaken the vessel wall.

Cholesterol relies on lipoproteins (LDLs and HDLs) for transport in the blood. The LDLs, which are atherogenic, carry cholesterol to the peripheral tissues. The HDLs, which are protective, remove cholesterol from the tissues and carry it back to the liver for disposal (reverse cholesterol transport). LDL receptors play a major role in removing cholesterol from the blood; persons with reduced numbers of receptors are at particularly high risk for development of atherosclerosis.

Atherosclerosis, a leading cause of death in the United States, affects large and medium-sized arteries, such as the coronary and cerebral arteries. It has an insidious onset, and its lesions usually are far advanced before symptoms appear. Although the mechanisms of atherosclerosis are uncertain, risk factors associated with its development have been identified. These include factors such as heredity, sex,
and age, which cannot be controlled, and factors such as smoking, high blood pressure, high serum cholesterol levels, diabetes, obesity, and inflammation, which can be controlled or modified.

The vasculitides are a group of vascular disorders characterized by vasculitis or inflammation and necrosis of the blood vessels in various tissues and organs of the body. They can be caused by injury to the vessel, infectious agents, or immune processes or can occur secondary to other disease states such as systemic lupus erythematosus.

Occlusive disorders interrupt arterial flow of blood and interfere with the delivery of oxygen and nutrients to the tissues. Occlusion of flow can result from a thrombus, emboli, vessel compression, vasospasm, or structural changes in the vessel. Peripheral arterial diseases affect blood vessels outside the heart and thorax. They include Raynaud disease or phenomenon, caused by vessel spasm, and thromboangiitis obliterans (Buerger disease), characterized by an inflammatory process that involves medium-sized arteries.

Aneurysms are localized areas of vessel dilation caused by weakness of the arterial wall. A berry aneurysm, most often found in the circle of Willis in the brain circulation, consists of a small, spherical vessel dilation. Fusiform and saccular aneurysms, most often found in the thoracic and abdominal aorta, are characterized by gradual and progressive enlargement of the aorta. They can involve part of the vessel circumference (saccular) or extend to involve the entire circumference of the vessel (fusiform). A dissecting aneurysm is an acute, life-threatening condition. It involves hemorrhage into the vessel wall with longitudinal tearing (dissection) of the vessel wall to form a blood-filled channel. The most serious consequence of aneurysms is rupture.

Veins are low-pressure, thin-walled vessels that rely on the ancillary action of skeletal muscle pumps and changes in abdominal and intrathoracic pressure to return blood to the heart. The venous system in the legs consists of two components—the superficial veins (i.e., saphenous vein and its tributaries) and the deep venous channels. Perforating, or communicating, veins connect these two systems. Blood from the skin and subcutaneous tissues in the leg collects in the superficial veins and is then transported across the communicating veins into the deeper venous channels for return to the heart.

Unlike the arterial system, the venous system is equipped with valves that prevent retrograde flow of blood. These valves play an important role in the function of the venous system. Although these valves are irregularly located along the length of the veins, they almost always are found at junctions where the communicating veins merge with the larger deep veins and where two veins meet. The number of venous valves differs somewhat from one person to another, as does their structural competence. These factors may help explain the familial predisposition to development of varicose veins.

The action of the leg muscles assists in moving venous blood from the lower extremities back to the heart. When a person walks, the action of the leg muscles serves to increase flow in the deep venous channels and return venous blood to the heart (Fig. 30.14). The function of the so-called muscle pump, located in the gastrocnemius and soleus muscles of the lower extremities, can be compared with the pumping action of the heart. During muscle contraction, which is similar to systole, valves in the communicating channels close to prevent backward flow of blood into the superficial system, as blood in the deep veins is moved forward by the action of the contracting muscles. During muscle relaxation, which is similar to diastole, the communicating valves open, allowing blood from the superficial veins to move into the deep veins.

Although its structure enables the venous system to serve as a storage area for blood, it also renders the system susceptible to problems related to stasis and venous insufficiency.
This section focuses on three common problems of the venous system—varicose veins, venous insufficiency, and venous thrombosis.

**KEY POINTS**

**DISORDERS OF THE VENOUS CIRCULATION**

- Veins are thin-walled, distensible vessels that collect blood from the tissues and return it to the heart. The venous system is a low-pressure system that relies on the pumping action of the skeletal muscles to move blood forward and the presence of venous valves to prevent retrograde flow.
- Disorders of the venous system produce congestion of the affected tissues and predispose to clot formation because of stagnation of flow and activation of the clotting system.

**Varicose Veins**

Varicose, or dilated, tortuous veins of the lower extremities are common and often lead to secondary problems of venous insufficiency. Varicose veins are described as being primary or secondary. Primary varicose veins originate in the superficial saphenous veins, and secondary varicose veins result from impaired flow in the deep venous channels. Approximately 80% to 90% of venous blood from the lower extremities is transported through the deep channels. The development of secondary varicose veins becomes inevitable when flow in these deep channels is impaired or blocked. The most common cause of secondary varicose veins is deep vein thrombosis (DVT). Other causes include congenital or acquired arteriovenous (AV) fistulas, congenital venous malformations, and pressure on the abdominal veins caused by pregnancy or a tumor.

The incidence of varicose veins rises with age. The prevalence of varicose veins is 50% in people older than 50 years. The condition is more common in females between 30 and 60 years of age, especially if there is a strong familial predisposition. There is also a higher incidence in obese people due to the increase in intra-abdominal pressure and among people who stand for the majority of their day due to an occupation (e.g., nurses).

**Etiology and Pathogenesis**

Prolonged standing and increased intra-abdominal pressure are important contributing factors in the development of primary varicose veins. Prolonged standing increases venous pressure and causes dilation and stretching of the vessel wall. One of the most important factors in the elevation of venous pressure is the hydrostatic effect associated with the standing position. When a person is in the erect position, the full weight of the venous columns of blood is transmitted to the leg veins. The effects of gravity are compounded in people who stand for long periods without using their leg muscles to assist in pumping blood back to the heart.

Because there are no valves in the inferior vena cava or common iliac veins, blood in the abdominal veins must be supported by the valves located in the external iliac or femoral veins. When intra-abdominal pressure increases, as it does during pregnancy, or when the valves in these two veins are absent or defective, the stress on the saphenofemoral junction is increased. The high incidence of varicose veins in women who have been pregnant also suggests a hormonal effect on venous smooth muscle contributing to venous dilation and valvular incompetence. Lifting also increases intra-abdominal pressure and decreases flow of blood through the abdominal veins. Occupations that require repeated heavy lifting also predispose to development of varicose veins.

Prolonged exposure to increased pressure causes the venous valves to become incompetent so they no longer close properly. When this happens, the reflux of blood causes further venous enlargement, pulling the valve leaflet apart and causing more valvular incompetence in sections of adjacent distal veins. Another consideration in the development of varicose veins is the fact that the superficial veins have only subcutaneous fat and superficial fascia for support, but the deep venous channels are supported by muscle, bone, and connective tissue. Obesity reduces the support provided by the superficial fascia and tissues, increasing the risk for development of varicose veins.

**Clinical Manifestations**

The signs and symptoms associated with primary varicose veins vary. Most women with superficial varicose veins complain of their unsightly appearance. In many cases, aching in the lower extremities and edema, especially after long periods of standing, may occur. The edema usually subsides at night when the legs are elevated. When the communicating veins are incompetent, symptoms are more common.

**Diagnosis and Treatment**

The diagnosis of varicose veins often can be made after a thorough history and physical examination, especially inspection of the extremities involved. Several procedures are used to assess the extent of venous involvement associated with varicose veins but have been shown to have limited value. One of the more helpful tests is the Perthes test. In this test, a tourniquet is applied to the affected knee while the person is instructed to complete 10 heel raises, and the leg is evaluated. If the varicosities empty, the site of reflux is above the tourniquet. If the veins remain distended, the site of reflux is below the tourniquet. The Doppler ultrasonic flow probe also may be used to assess flow in the large vessels. Angiographic studies using a radiopaque contrast medium also are used to assess venous function.79

After the venous channels have been repeatedly stretched and the valves rendered incompetent, little can be done to restore normal venous tone and function. Ideally, measures should be taken to prevent the development and progression of varicose veins. This would include weight loss and measures...
center on avoiding activities such as continued standing that produce prolonged elevation of venous pressure.

Treatment measures for varicose veins focus on improving venous flow and preventing tissue injury. When correctly fitted, elastic support stockings or leggings compress the superficial veins and prevent distention. Prescription stockings measured to fit properly afford the most precise control. These stockings should be applied before the standing position is assumed, when the leg veins are empty.29

Sclerotherapy, which often is used in the treatment of small residual varicosities, involves the injection of a sclerosing agent into the collapsed superficial veins to produce fibrosis of the vessel lumen. Surgical treatment consists of removing the varicosities and the incompetent perforating veins, but it is limited to people with patent deep venous channels.

**Chronic Venous Insufficiency**

The term *venous insufficiency* refers to the physiologic consequences of DVT, valvular incompetence, or a combination of both conditions. The most common cause is DVT, which causes deformity of the valve leaflets, rendering them incapable of closure. In the presence of valvular incompetence, effective unidirectional flow of blood and emptying of the deep veins cannot occur. The muscle pumps also are ineffective, often driving blood in retrograde directions. Secondary failure of the communicating and superficial veins subjects the subcutaneous tissues to high pressures.

With venous insufficiency, there are signs and symptoms associated with impaired blood flow. In contrast to the ischemia caused by arterial insufficiency, venous insufficiency leads to tissue congestion, edema, and eventual impairment of tissue nutrition.30 The edema is exacerbated by long periods of standing. Necrosis of subcutaneous fat deposits occurs, followed by skin atrophy. Brown pigmentation of the skin caused by hemosiderin deposits resulting from the breakdown of red blood cells is common. Secondary lymphatic insufficiency occurs, with progressive sclerosis of the lymph channels in the face of increased demand for clearance of interstitial fluid.

In advanced venous insufficiency, impaired tissue nutrition causes stasis dermatitis and the development of stasis or venous ulcers (Fig. 30.15). Stasis dermatitis is characterized by the presence of thin, shiny, bluish brown, irregularly pigmented desquamative skin that lacks the support of the underlying subcutaneous tissues. Minor injury leads to relatively painless ulcerations that are difficult to heal. The lower part of the leg is particularly prone to development of stasis dermatitis and venous ulcers. Most lesions are located medially over the ankle and lower leg, with the highest frequency just above the medial malleolus. Venous insufficiency is the most common cause of lower leg ulcers, accounting for nearly 80% of all cases.31 The other common causes of lower extremity ulcers are arterial insufficiency, neuropathy (often due to diabetes), and pressure ulcers. People with long-standing venous insufficiency may also experience stiffening of the ankle joint and loss of muscle mass and strength.

Treatment of venous ulcers includes compression therapy with dressings and inelastic or elastic bandages. Medications that help include aspirin and pentoxifylline. Occasionally skin grafting is required for large or slow-healing venous ulcers. Growth factors (which are administered topically or by perilesional injection) may also be warranted.31

**Venous Thrombosis**

The term *venous thrombosis*, or *thrombophlebitis*, describes the presence of thrombus in a vein and the accompanying inflammatory response in the vessel wall. Thrombi can develop in the superficial or the deep veins. Superficial venous thrombosis can occur on any superficial vein and in the past, was thought to be a benign disease. Recently, SVT has been found to lead to complications such as reoccurrence of SVT, DVT, and pulmonary embolism in 10% of people.32 DVT most commonly occurs in the lower extremities. DVT of the lower extremity is a serious disorder, complicated by pulmonary embolism, recurrent episodes of DVT, and development of chronic venous insufficiency. Most postoperative thrombi arise in the soleal sinuses or the large veins draining the gastrocnemius muscles.3 Isolated calf thrombi often are asymptomatic. If left untreated, they may extend to the larger, more proximal veins, with an increased risk of pulmonary emboli of up to 90%.5
Etiology and Pathogenesis

Venous thrombosis is associated with stasis of blood, increased blood coagulability, and vessel wall injury. Stasis of blood occurs with immobility of an extremity or the entire body. Bed rest and immobilization are associated with decreased blood flow, venous pooling in the lower extremities, and increased risk of DVT. People who are immobilized by a hip fracture, joint replacement, or spinal cord injury are particularly vulnerable to DVT. The risk of DVT is increased in situations of impaired cardiac function. This may account for the relatively high incidence in people with acute myocardial infarction and congestive heart failure. Older adults are more susceptible than younger people, probably because disorders that produce venous stasis occur more frequently in older adults. Long airplane travel poses a particular threat in people predisposed to DVT because of prolonged sitting and increased blood viscosity due to dehydration.

Hypercoagulability is a homeostatic mechanism designed to increase clot formation, and conditions that increase the concentration or activation of clotting factors predispose to DVT. Thrombosis also can be caused by inherited or acquired deficiencies in certain plasma proteins that normally inhibit thrombus formation, such as antithrombin III, protein C, and protein S. However, the most common inherited risk factors are the factor V Leiden and prothrombin gene mutations. The use of oral contraceptives and hormone replacement therapy appears to increase coagulability and predispose to venous thrombosis, a risk that is further increased in women who smoke. Certain cancers are associated with increased clotting tendencies, and although the reason for this is largely unknown, substances that promote blood coagulation may be produced by the tumor cells or released from the surrounding tissue in response to the cancerous growth. Immune interactions with cancer cells can result in the release of cytokines that can cause endothelial damage and predispose to thrombosis. When body fluid is lost because of injury or disease, the resulting hemoconcentration causes clotting factors to become more concentrated. Other important risk factors include the antiphospholipid syndrome and myeloproliferative disorders.

Vessel injury can result from a trauma situation or from surgical intervention. It also may occur secondary to infection or inflammation of the vessel wall. People undergoing hip surgery and total hip replacement are at particular risk because of trauma to the femoral and iliac veins and, in the case of hip replacement, thermal damage from heat generated by the polymerization of the acrylic cement that is used in the procedure. Venous catheters are another source of vascular injury. Risk factors for venous thrombosis are summarized in Chart 30.1.

Clinical Manifestations

Many people with venous thrombosis are asymptomatic; as much as 50% of people with DVT are asymptomatic. Lack of signs and symptoms is probably because the vein is not totally occluded or because of collateral circulation. When present, the most common signs and symptoms of venous thrombosis are those related to the inflammatory process, including pain, swelling, and deep muscle tenderness. Fever, general malaise, and an elevated white blood cell count and erythrocyte sedimentation rate are accompanying indications of inflammation. There may be tenderness and pain along the vein. Swelling may vary from minimal to maximal.

The site of thrombus formation determines the location of the physical findings. The most common site is in the venous sinuses in the soleus muscle and posterior tibial and peroneal veins. Swelling in these cases involves the foot and ankle, although it may be slight or absent. Calf pain and tenderness are common. Femoral vein thrombosis produces pain and tenderness in the distal thigh and popliteal area. Thrombi in iliofemoral veins produce the most profound manifestations, with swelling, pain, and tenderness of the entire extremity.

Diagnosis and Treatment

The risk of pulmonary embolism emphasizes the need for early detection and treatment of DVT. Several tests are useful for this purpose, including ascending venography, ultrasonography (e.g., real-time, B-mode, duplex), and plasma d-dimer assessment.
Whenever possible, venous thrombosis should be prevented in preference to being treated. Early ambulation after childbirth and surgery is one measure that decreases the risk of thrombus formation. Exercising the legs and wearing support stockings improve venous flow. A further precautionary measure is to avoid assuming body positions that favor venous pooling. Antiembolism stockings of the proper fit and length should be used routinely in people at risk for DVT. Another strategy used for immobile people at risk for development of DVT is a sequential pneumatic compression device. This consists of a plastic sleeve that encircles the legs and provides alternating periods of compression on the lower extremity. When properly used, these devices enhance venous emptying to augment flow and reduce stasis. Prophylactic anticoagulation drug therapy often is used in people who are at high risk for development of venous thrombi.

The objectives of treatment of venous thrombosis are to prevent the formation of additional thrombi, prevent extension and embolization of existing thrombi, and minimize venous valve damage. A 15- to 20-degree elevation of the legs prevents stasis. It is important that the entire lower extremity or extremities be carefully extended to avoid acute flexion of the knee or hip. Heat often is applied to the leg to relieve venospasm and to aid in the resolution of the inflammatory process. Bed rest usually is maintained until local tenderness and swelling have subsided. Gradual ambulation with elastic support is then permitted. Standing and sitting increase venous pressure and are to be avoided. Elastic support is needed for 3 to 6 months to permit recanalization and collateralization and to prevent venous insufficiency.

Anticoagulation drug therapy (i.e., heparin and warfarin) is used to treat and prevent venous thrombosis. Treatment typically is initiated with either continuous intravenous infusion of heparin followed by prophylactic therapy with oral anticoagulants to prevent further thrombus formation or with subcutaneous injections of low molecular weight heparin (LMWH). LMWH may also be given on an outpatient basis.29 Thrombolytic therapy (i.e., streptokinase, urokinase, or tissue plasminogen activator) may be used in an attempt to dissolve the clot.

Surgical removal of the thrombus may be undertaken in selected cases. Percutaneous (through the skin) insertion of intracaval filters improve venous flow. This procedure prevents large clots from moving through the vessel. However, although filters prevent the development of pulmonary emboli, an increase in thrombosis occurs at the site of the filter itself in the absence of anticoagulation.

IN SUMMARY

The storage function of the venous system renders it susceptible to venous insufficiency, stasis, and thrombus formation. Varicose veins occur with prolonged distention and stretching of the superficial veins owing to venous insufficiency. Varicosities can arise because of defects in the superficial veins (i.e., primary varicose veins) or because of impaired blood flow in the deep venous channels (i.e., secondary varicose veins). Venous insufficiency reflects chronic venous stasis resulting from valvular incompetence. It is associated with stasis dermatitis and stasis or venous ulcers. Venous thrombosis describes the presence of thrombus in a vein and the accompanying inflammatory response in the vessel wall. It is associated with vessel injury, stasis of venous flow, and hypercoagulability states. Thrombi can develop in the superficial or the deep veins (i.e., DVT). Thrombus formation in deep veins is a precursor to venous insufficiency and embolus formation.

REVIEW EXERCISES

1. The Third Report of the NCEP Expert Panel on Detection, Evaluation, and Treatment of High Cholesterol in Adults recommends that a person’s HDL should be above 40 mg/dL.
   A. Explain the role of HDL in prevention of atherosclerosis.

2. A 55-year-old male executive presents at the clinic for his regular checkup. He was diagnosed with hypertension 5 years ago and has been taking a diuretic and a β-adrenergic blocker to control his blood pressure. His blood pressure is currently being maintained at about 135/70 mm Hg. His total cholesterol level is 180 mg/dL, and his HDL cholesterol is 30 mg/dL. He is otherwise well. He is a nonsmoker. He has recently read in the media about “inflammation” and the heart and expresses concern about his risk of CHD.
   A. Use the risk assessment tool based on the Framingham Heart Study to calculate this man’s 10-year risk of developing myocardial infarction and coronary death (available at www.nhlbi.nih.gov/guidelines/cholesterol/).

3. A 62-year-old man presents at the emergency department of his local hospital with complaints of excruciating, “ripping” pain in his upper back. He has a history of poorly controlled hypertension. His radial pulse and blood pressure, which on admission were 92 and 140/80 mm Hg, respectively, become unobtainable in both arms. A transesophageal echocardiogram reveals a dissection of the descending aorta. Aggressive blood pressure control is initiated with the goal of reducing the systolic pressure and pulsatile blood flow (pulse pressure).
   A. Explain how aortic dissection differs from a thoracic aorta aneurysm.
   B. Explain the role of poorly controlled hypertension as an etiologic factor in dissecting aneurysms.
C. Why did his radial pulse and blood pressure become unobtainable?
D. Explain the need for aggressive control of aortic pressure and pulsatile blood flow.

4. A 34-year-old, otherwise healthy woman complains of episodes lasting several hours in which her fingers become pale and numb. This is followed by a period during which the fingers become red, throbbing, and painful. She lives in the Northeast and notices it more in the fall and winter months.

A. What do you think is causing this woman’s problem?
B. She relates that the episodes often occur when her fingers become cold or when she becomes upset. Explain the possible underlying mechanisms.
C. What types of measures could be used to treat this woman?

Diagnosis

Treatment

Blood pressure is probably one of the most variable but best-regulated functions of the body. The purpose of the control of blood pressure is to keep blood flow constant to vital organs such as the heart, brain, and kidneys. Without constant blood flow to these organs, death ensues within seconds, minutes, or days. Although a decrease in flow produces an immediate threat to life, the continuous elevation of blood pressure that occurs with hypertension is a contributor to premature death and disability because of its effects on the heart, blood vessels, and kidneys.

The discussion in this chapter focuses on determinants of blood pressure and conditions of altered arterial pressure—hypertension and orthostatic hypotension.

**THE ARTERIAL BLOOD PRESSURE**

After completing this section of the chapter, you should be able to meet the following objectives:

- Define the terms systolic blood pressure, diastolic blood pressure, pulse pressure, and mean arterial blood pressure.
- Explain how cardiac output and peripheral vascular resistance interact in determining systolic and diastolic blood pressure.

The arterial blood pressure reflects the rhythmic ejection of blood from the left ventricle into the aorta. It rises during systole as the left ventricle contracts and falls as the heart relaxes during diastole. The contour of the arterial pressure tracing shown in Figure 31.1 is typical of the pressure changes that occur in the large arteries of the systemic circulation. There is a rapid rise in the pulse contour during left ventricular contraction, followed by a slower rise to peak pressure. Approximately 70% of the blood that leaves the left ventricle is ejected during the first one third of systole, accounting for
peripheral vascular resistance, and can be expressed as the product of the two (mean arterial blood pressure = cardiac output × peripheral vascular resistance). The peripheral vascular resistance reflects changes in the radius of the arterioles as well as the viscosity or thickness of the blood. The arterioles often are referred to as the resistance vessels because they can selectively constrict or relax to control the resistance to outflow of blood into the capillaries. The body maintains its blood pressure by adjusting the cardiac output to compensate for changes in peripheral vascular resistance and changes the peripheral vascular resistance to compensate for changes in cardiac output.

In hypertension and disease conditions that affect blood pressure, changes in blood pressure usually are described in terms of the systolic and diastolic pressures, pulse pressure, and mean arterial pressure. These pressures are influenced by the stroke volume, the rapidity with which blood is ejected from the heart, the elastic properties of the aorta and large arteries and their ability to accept various amounts of blood as it is ejected from the heart, and the properties of the resistance blood vessels that control the runoff of blood into the smaller vessels and capillaries that connect the arterial and venous circulations.

**Mechanisms of Blood Pressure Regulation**

Although different tissues in the body are able to regulate their own blood flow, it is necessary for the arterial pressure to remain relatively constant as blood shifts from one area of the body to another. The mechanisms used to regulate the arterial pressure depend on whether acute control or long-term control is needed (see Fig. 31.2).

**Acute Regulation**

The mechanisms for acute regulation of blood pressure, those acting over seconds to minutes, are intended to correct temporary imbalances in blood pressure, such as occur during physical exercise and changes in body position. These mechanisms also are responsible for maintenance of blood pressure at survival levels during life-threatening situations such as during an acute hemorrhagic incident. The acute control of blood pressure relies mainly on neural and humoral mechanisms, the most rapid of which are the neural mechanisms.

**Neural Mechanisms.** The neural control centers for the regulation of blood pressure are located in the reticular formation of the medulla and lower third of the pons, where integration and modulation of autonomic nervous system (ANS) responses occur. This area of the brain contains the vasomotor and cardiac control centers and is often collectively referred to as the cardiovascular center. The cardiovascular center transmits parasympathetic impulses to the heart through the vagus nerve and sympathetic impulses to the heart and blood vessels through the spinal cord and peripheral sympathetic nerves. Vagal stimulation of the heart produces a slowing of heart rate, whereas sympathetic stimulation...
produces an increase in heart rate and cardiac contractility. Blood vessels are selectively innervated by the sympathetic nervous system (SNS). Increased sympathetic activity produces constriction of the small arteries and arterioles with a resultant increase in peripheral vascular resistance.

The ANS control of blood pressure is mediated through intrinsic circulatory reflexes, extrinsic reflexes, and higher neural control centers. The intrinsic reflexes, including the baroreceptor and chemoreceptor reflexes, are located in the circulatory system and are essential for rapid and short-term regulation of blood pressure. The sensors for extrinsic reflexes are found outside the circulation. They include blood pressure responses associated with factors such as pain and cold. The neural pathways for these reactions are more diffuse, and their responses are less consistent than those of the intrinsic reflexes. Many of these responses are channeled through the hypothalamus, which plays an essential role in the control of SNS responses. Among higher-center responses are those caused by changes in mood and emotion.

The baroreceptors or pressoreceptors are pressure-sensitive receptors located in the walls of blood vessels and the heart. The carotid and aortic baroreceptors are located in strategic positions between the heart and the brain (Fig. 31.3). They respond to changes in the stretch of the vessel wall by sending impulses to cardiovascular centers in the brain stem to effect appropriate changes in heart rate, rate of contraction, and vascular smooth muscle tone. For example, the fall in blood pressure that occurs on moving from the lying to the standing position produces a decrease in the stretch of the baroreceptors with a resultant increase in heart rate and sympathetically induced vasoconstriction that causes an increase in peripheral vascular resistance.

The arterial chemoreceptors are chemosensitive cells that monitor the oxygen, carbon dioxide, and hydrogen ion content of the blood. They are located in the carotid bodies, which lie in the bifurcation of the two common carotids, and in the aortic bodies of the aorta (see Fig. 31.3). Because of their location, these chemoreceptors are always in close contact with the arterial blood. Although the main function of the chemoreceptors is to regulate ventilation, they also communicate with cardiovascular centers in the brain stem and can induce widespread vasoconstriction. Whenever the arterial pressure drops below a critical level, the chemoreceptors are stimulated because of diminished oxygen supply and a buildup of carbon dioxide and hydrogen ions. In people with chronic lung disease, systemic and pulmonary hypertension may develop because of hypoxemia. People with sleep apnea also may experience an increase in blood pressure because of the hypoxemia that occurs during the apneic periods.

**Humoral Mechanisms.** A number of humoral mechanisms contribute to blood pressure regulation, including the

**FIGURE 31.2** - Mechanisms of blood pressure regulation. The solid lines represent the mechanisms for renal and baroreceptor control of blood pressure through changes in cardiac output and peripheral vascular resistance. The dashed lines represent the stimulus for regulation of blood pressure by the baroreceptors and the kidneys.
Angiotensin II also reduces sodium excretion by increasing sodium reabsorption by the proximal tubules of the kidney. A second major function of angiotensin II, stimulation of aldosterone secretion from the adrenal gland, contributes to the long-term regulation of blood pressure by increasing salt and water retention by the kidney.

Vasopressin, also known as antidiuretic hormone (ADH), is released from the posterior pituitary gland in response to decreases in blood volume and blood pressure, an increase in the osmolality of body fluids, and other stimuli. The renin–angiotensin–aldosterone system, vasopressin, and epinephrine/norepinephrine. These substances acutely regulate blood pressure by altering the vascular tone. Norepinephrine/epinephrine also modifies blood pressure by increasing heart rate and cardiac contractility.

The renin–angiotensin–aldosterone system plays a central role in blood pressure regulation. Renin is an enzyme that is synthesized, stored, and released by the juxtaglomerular cells of the kidneys in response to an increase in SNS activity or a decrease in blood pressure, extracellular fluid volume, or extracellular sodium concentration. Most of the renin that is released leaves the kidney and enters the bloodstream, where it acts enzymatically to convert an inactive circulating plasma protein called angiotensinogen to angiotensin I (Fig. 31.4). Angiotensin I is then converted to angiotensin II. This conversion occurs almost entirely in the lungs, while blood flows through the small vessels of the lung, catalyzed by an enzyme called the angiotensin-converting enzyme (ACE) that is present in the endothelium of the lung vessels. Although angiotensin II has a half-life of only several minutes, renin persists in the circulation for 30 minutes to 1 hour and continues to cause production of angiotensin II during this time.

Angiotensin II functions in both the short- and long-term regulation of blood pressure. It is a strong vasoconstrictor, particularly of arterioles and, to a lesser extent, of veins. Constriction of the arterioles increases the peripheral vascular resistance, thereby contributing to the short-term regulation of blood pressure. Angiotensin II also reduces sodium excretion by increasing sodium reabsorption by the proximal tubules of the kidney. A second major function of angiotensin II, stimulation of aldosterone secretion from the adrenal gland, contributes to the long-term regulation of blood pressure by increasing salt and water retention by the kidney.

Vasopressin, also known as antidiuretic hormone (ADH), is released from the posterior pituitary gland in response to decreases in blood volume and blood pressure, an increase in the osmolality of body fluids, and other stimuli. The
Arterial Blood Pressure

The arterial blood pressure represents the force that distributes blood to the capillaries throughout the body. The highest arterial pressure is the systolic pressure and the lowest is the diastolic pressure. The aorta and its major branches constitute a system of conduits between the heart and the arterioles. The arterioles, which are the terminal components of the arterial system, serve as resistance vessels that regulate the blood pressure at the distribution of blood to the capillary beds. Because the normal arteries are so compliant and the arterioles present such high resistance to flow, the arterial system acts as a filter that converts the intermittent flow generated by the heart into a virtually steady flow through the capillaries. The low-pressure venous system collects blood from the capillaries and returns it to the heart as a means of maintaining the cardiac output needed to sustain arterial pressure.

Systolic Pressure

The systolic blood pressure reflects the amount of blood (stroke volume) that is ejected from the heart with each beat, the rate and force with which it is ejected, and the elasticity or compliance of the aorta and large arteries. The blood that is ejected from the heart during systole does not move directly through the circulation. Instead, a substantial fraction of the stroke volume is stored in large arteries. Because the walls of these vessels are elastic, they can be stretched to accommodate a large volume of blood without an appreciable change in pressure. The systolic pressure often increases with aging as the aorta and large arteries lose their elasticity and become more rigid.

Determinants of Blood Pressure

The arterial blood pressure, which is the force that moves blood through the arterial system, reflects the intermittent contraction and relaxation of the left ventricle. It is determined by (1) the properties of the arterial system and the factors that maintain (2) the systolic and (3) the diastolic components of the blood pressure. These factors include the blood volume, elastic properties of the blood vessels, cardiac output, and peripheral vascular resistance.
**Diastolic Pressure**

The diastolic blood pressure reflects the closure of the aortic valve, the energy that has been stored in the elastic fibers of the large arteries during systole, and the resistance to flow through arterioles into the capillaries. Closure of the aortic valve at the onset of diastole and recoil of the elastic fibers in the aorta and large arteries continue to drive the blood forward, even though the heart is not pumping. These effects, largely restricted to the elastic vessels, convert the discontinuous systolic flow in the ascending aorta into a continuous flow in the peripheral arteries.

---

antidiuretic actions of vasopressin are discussed in Chapter 39. Vasopressin has a direct vasoconstrictor effect, particularly on the vessels of the splanchnic circulation that supplies the abdominal viscera. However, long-term increases in vasopressin cannot maintain an increase in blood pressure, and vasopressin does not enhance hypertension produced by sodium-retaining hormones or other vasoconstricting substances. It has been suggested that vasopressin plays a permissive role in hypertension through its water-retaining properties or as a neurotransmitter that serves to modify ANS function.

Epinephrine and, to a lesser extent, norepinephrine are released from the adrenal gland into the bloodstream when the sympathetic nervous system is activated. They increase blood pressure by inducing vasoconstriction and by increasing heart rate and cardiac contractility.

**Long-Term Regulation**

Long-term mechanisms control the daily, weekly, and monthly regulation of blood pressure. Although the neural and hormonal mechanisms involved in the short-term regulation of blood pressure act rapidly, they are unable to maintain their effectiveness over time. Instead, the long-term regulation of blood pressure is largely vested in the kidneys and their role in the regulation of the extracellular fluid volume.¹

Extracellular fluid volume and arterial blood pressure are regulated around an equilibrium point, which represents the normal pressure for a given individual.¹ When the body contains excess extracellular fluids because of increased water and salt intake, the arterial pressure rises, and the rate at which water (i.e., *pressure diuresis*) and salt (i.e., *pressure natriuresis*) are excreted by the kidney is increased. Accordingly, there are two ways that arterial pressure can be increased using this model: one is by shifting the elimination of salt and water to a higher pressure level and the second is by changing the extracellular fluid level at which diuresis and natriuresis occur. The function of the kidneys in the long-term regulation of blood pressure can be influenced by a number of factors. For example, excess sympathetic nerve activity or the release of vasoconstrictor substances can alter the transmission of arterial pressure to the kidney. Similarly, changes in neural and humoral control of kidney function can shift the diuresis–natriuresis process to a higher fluid or pressure level, thereby initiating an increase in arterial pressure.

There are two general mechanisms by which an increase in fluid volume can elevate blood pressure. One is through a direct effect on cardiac output and the other is indirect, resulting from the autoregulation of blood flow and its effect on peripheral vascular resistance. Autoregulatory mechanisms function in distributing blood flow to the various tissues of the
body according to their metabolic needs. When the blood flow to a specific tissue bed is excessive, local blood vessels constrict, and when the flow is deficient, the local vessels dilate. In situations of increased extracellular fluid volume and a resultant increase in cardiac output, all of the tissues of the body are exposed to the same increase in flow. This results in a generalized constriction of arterioles and an increase in the peripheral vascular resistance (and blood pressure).

The role that the kidneys play in blood pressure regulation is emphasized by the fact that many antihypertensive medications produce their blood pressure-lowering effects by increasing sodium and water elimination.

**Circadian Variations in Blood Pressure**

These acute and chronic mechanisms attempt to regulate blood pressure around a particular set point. However, this set point varies in a characteristic circadian pattern. It tends to be highest shortly after awakening in the morning, and then decreases gradually throughout the day and night, reaching its lowest point at approximately 2:00 to 5:00 AM.4,6 The term *dippers* is used to refer to people with a normal circadian blood pressure profile in which blood pressure falls during the night, and *nondippers* for people whose 24-hour blood pressure profile is flattened.6

**Blood Pressure Measurement**

Arterial blood pressure measurements usually are obtained by the indirect auscultatory method, which uses a stethoscope and a well-calibrated sphygmomanometer. In the measurement of blood pressure, a cuff that contains an inflatable rubber bladder is placed preferably around the upper arm. People should be seated and should not have ingested caffeine or have smoked 30 minutes before the measurement.2 The bladder of the cuff is inflated to a point at which its pressure exceeds that of the artery, occluding the blood flow. This should be done by palpation before the actual pressure is measured to get the palpated systolic pressure. By inflating the pressure in the cuff to a level of 30 mm Hg above the palpated pressure, the observer can be certain that the cuff pressure is high enough to avoid missing the auscultatory gap. This pressure (palsatped pressure + 30 mm Hg) is called the *maximum inflation level.*3 The cuff is then slowly deflated at 2 mm Hg per second. At the point where the pressure in the vessel again exceeds the pressure in the cuff, a small amount of blood squirts through the partially obstructed artery. The sounds generated by the turbulent flow are called the *Korotkoff (K) sounds.* These low-pitched sounds are best heard with the bell of the stethoscope. Blood pressure is recorded in terms of systolic and diastolic pressures (e.g., 120/70 mm Hg) unless sounds are heard to zero, in which case three readings are required (122/64/0 or K1/K4/K5). Systolic pressure is defined as the first of two or more Korotkoff sounds heard (K1). Diastolic pressure is recorded as the last sound heard (K5) unless sounds are heard to zero, in which case the muffling sound of K4 is used.

It is important that the bladder of the cuff be appropriate for the arm size. The width of the bladder should be at least 40% of arm circumference and the length at least 80% of arm circumference. Miscuffing, which includes undercuffing (using a cuff with a bladder that is too small) and overcuffing (using a cuff with a bladder that is too large) can cause blood pressure to be over- and underestimated. Underestimating would mislabel people prehypertensive when they are hypertensive, and overestimating would lead to inappropriate treatment with antihypertensive medications.7

**Automated or semiautomated methods** of blood pressure measurement use a microphone, arterial pressure pulse sensor (oscillometric method), or Doppler equipment for detecting the equivalent of the Korotkoff sounds. Oscillometric measurement, the most commonly used method, depends on the detection of the pulsatile oscillations of the brachial artery in the blood pressure cuff.8 In contrast to the auscultatory method, this method determines the mean arterial pressure based on the amplitude of the arterial pulsations and then uses an algorithm to calculate the systolic and diastolic pressures. Blood pressures obtained by automated devices are usually less accurate than those obtained by trained observers using the auscultatory method, and it is recommended that their use be limited to situations in which frequent and less accurate measures of blood pressure trends are needed. They should not be used for the diagnosis and management of hypertension.9

Automated devices are useful for the self-monitoring of blood pressure and for 24-hour ambulatory monitoring of blood pressure.9,10 Ambulatory blood monitors are fully automatic and can record blood pressure for 24 hours or longer while people go about their normal activities. The monitors are typically programmed to take readings every 15 to 30 minutes throughout the day and night. The readings are stored and downloaded into a computer for analysis. This can be important information when there is a problem with the drug therapy. It is important that the equipment be certified as accurate and reliable. The equipment should be a validated aneroid or electronic monitor, should use an appropriate-size cuff, and be checked at least once a year for accuracy. The accuracy of an electronic device can be checked by comparing its readings with simultaneously obtained auscultatory measurements.

**Intra-arterial methods** provide for direct measurement of blood pressure. Intra-arterial measurement requires the insertion of a catheter into a peripheral artery. The arterial catheter is connected to a pressure transducer, which converts pressure into a digital signal that can be measured, displayed, and recorded. The use of this type of blood pressure monitoring usually is restricted to intensive care units.

**IN SUMMARY**

The alternating contraction and relaxation of the heart produces a pressure pulse that moves blood through the circulatory system. The elastic walls of the aorta stretch during systole and relax during diastole to maintain the diastolic pressure. The systolic blood pressure denotes the highest point of the pressure pulse and the diastolic pressure the...
Chapter 31 Disorders of Blood Pressure Regulation

Hypertension, or high blood pressure, is probably the most common of all health problems in adults and is the leading risk factor for cardiovascular disorders. It affects approximately 50 million people in the United States and approximately 1 billion worldwide. Hypertension is more common in younger men compared with younger women. Men have higher blood pressures compared to women up until women reach menopause. At this point, women quickly lose their hormonal protection against hypertension. Hypertension is more common in blacks compared with whites, in people from lower socioeconomic groups, and in older adults. The prevalence of hypertension increases with age. Recent data from the Framingham Study suggest that people who are normotensive at 55 years of age have a 90% lifetime risk for development of hypertension.

Hypertension is commonly divided into the categories of primary and secondary hypertension. Primary (essential) hypertension is the term applied to 95% of cases in which no cause for hypertension can be identified. In secondary hypertension, the elevation of blood pressure results from an identifiable underlying secondary cause, such as kidney or endocrine disease.

Primary (Essential) Hypertension

The seventh report of the Joint National Committee on Detection, Evaluation, and Treatment of High Blood Pressure (JNC 7) of the National Institutes of Health was published in 2003. According to the JNC 7 recommendations, a systolic pressure of less than 120 mm Hg and a diastolic pressure of less than 80 mm Hg are normal, and systolic pressures between 120 and 139 mm Hg and diastolic pressures between 80 and 89 mm Hg are considered prehypertensive (Table 31.1). A diagnosis of hypertension is made if the systolic blood pressure is 140 mm Hg or higher and the diastolic blood pressure is 90 mm Hg or higher. For adults with diabetes mellitus, the blood pressure goal has been lowered to less than 130/80 mm Hg. Hypertension is further divided into stages 1 and 2 based on systolic and diastolic blood pressure measurements. Systolic hypertension (to be discussed) is defined as a systolic pressure of 140 mm Hg or greater and a diastolic pressure of less than 90 mm Hg.

Etiology and Pathogenesis

Although the cause or causes of essential hypertension are largely unknown, both constitutional and lifestyle factors have been implicated, either singly or collectively, as contributing factors.

Nonmodifiable Risk Factors. The constitutional risk factors include a family history of hypertension, age-related increases in blood pressure, and race. Another factor that is thought to contribute to hypertension is insulin resistance and hyperinsulinemia that occurs in metabolic abnormalities such as type 2 diabetes.

Family History. The inclusion of heredity as a contributing factor in the development of hypertension is supported by the fact that hypertension is seen most frequently among people with a family history of hypertension. It is thought that genetic
contribution to hypertension is up to 50%. The strength of the prediction depends on the definition of positive family history and environmental factors. Geneticists have not found common genes with large effects on hypertension. However, it is possible that multiple genes at many loci determine blood pressure, each gene having a small influence or with a contribution differing according to sex, race, age, and lifestyle.

Age-Related Changes in Blood Pressure. Maturation and growth are known to cause predictable increases in blood pressure. For example, the arterial blood pressure in the newborn is approximately 50 mm Hg systolic and 40 mm Hg diastolic. Sequentially, blood pressure increases with physical growth from a value of 78 mm Hg systolic at 10 days of age to 120 mm Hg at the end of adolescence. Diastolic pressure increases until 50 years of age and then declines from the sixth decade onward, whereas systolic blood pressure continues to rise with age.

Race. Hypertension not only is more prevalent in blacks than other ethnic groups in the United States, it is more severe. Hypertension also tends to occur at an earlier age in blacks than in whites and often is not treated early enough or aggressively enough. Blacks also tend to experience greater cardiovascular and renal damage at any level of pressure.

The reasons for the increased incidence of hypertension among blacks are largely unknown. Studies have shown that many black people with hypertension have lower renin levels than white people with hypertension. The suppression of renin has been considered a secondary response to sodium retention and volume excess. Salt sensitivity, defined as an increase in blood pressure in response to a high-salt diet, is commonly described in both normotensive and hypertensive blacks. Recent research has focused on potential defects in renal sodium transport to explain this observation. Other factors, such as increased vasomotor function (e.g., SNS overactivity) or abnormalities in endothelium-dependent vasodilation have also been suggested as possible contributing factors.

Evidence suggests that blacks, when provided equal access to diagnosis and treatment, can achieve overall reductions in blood pressure and experience fewer cardiovascular complications, similar to whites. With the high prevalence of salt sensitivity, obesity, and smoking among blacks, health education and lifestyle modifications are particularly important.

Insulin Resistance and Metabolic Abnormalities. Insulin resistance and an accompanying compensatory hyperinsulinemia have been suggested as possible etiologic links to the development of hypertension and associated metabolic disturbances such as impaired glucose tolerance, type 2 diabetes, hyperlipidemias, and obesity. This clustering of cardiovascular risk factors has been named the insulin resistance syndrome or metabolic syndrome.

Insulin resistance has been found to be more of an acquired trait than a genetic trait. For example, obesity plays an important role in the development of insulin resistance. Obesity affects the tissues’ sensitivity towards insulin. Nonpharmacologic interventions, such as caloric restriction, weight loss, and exercise, tend to decrease insulin resistance, SNS activity, and blood pressure.

Modifiable Risk Factors. Lifestyle factors can contribute to the development of hypertension by interacting with the constitutional risk factors. These lifestyle factors include high salt intake, excessive calorie intake and obesity, excessive alcohol consumption, and low intake of potassium. Although stress can raise blood pressure acutely, there is less evidence linking
it to chronic elevations in blood pressure. Smoking and a diet high in saturated fats and cholesterol, although not identified as primary risk factors for hypertension, are independent risk factors for coronary heart disease and should be avoided.

**High Salt Intake.** Increased salt intake has long been suspected as an etiologic factor in the development of hypertension. Just how increased salt intake contributes to the development of hypertension is still unclear. It may be that salt causes an elevation in blood volume, increases the sensitivity of cardiovascular or renal mechanisms to SNS influences, or exerts its effects through some other mechanism such as the renin–angiotensin–aldosterone system. It has also been suggested that it may be the chloride rather than the sodium in salt that is responsible for the rise in blood pressure. This is difficult to study, however, because 95% of sodium in the diet is in the form of sodium chloride.

Regardless of the mechanism, numerous studies have shown that a reduction in salt intake can lower blood pressure. The strongest data come from the INTERSALT study, which measured 24-hour urine sodium excretion (an indirect measure of salt intake) in 10,079 men and women 20 to 59 years of age in 52 locations around the world. In all 52 sites, there was a positive correlation between sodium excretion and both systolic and diastolic blood pressures. Furthermore, the association of sodium and blood pressure was greatest for older (40 to 59 years) people compared with younger (20 to 39 years) people in the study.

At present, salt intake among adults in the United States and United Kingdom averages at least 9 g/day, with large numbers of people consuming 12 g/day or more. This is far in excess of the maximal intake of 6 g/day for adults recommended by the American Heart Association. Approximately 75% of salt intake comes from salt added in the processing and manufacturing of food; 15% from the discretionary addition in cooking and at the table; and 10% from the natural sodium content of food. The Dietary Approaches to Stop Hypertension (DASH) diet is a nutritional plan that emphasizes fruits, vegetables, low-fat dairy products, whole grains, poultry, fish, and nuts, and is reduced in fat, red meat, sweets, and sugar-containing beverages. Results from studies using the low-sodium DASH diet have shown significant reductions in both systolic and diastolic blood pressures.

**Obesity.** The prevalence of obesity in the United States is increasing at alarming rates. Excessive weight commonly is associated with hypertension. Weight reduction of as little as 4.5 kg (10 lb) can produce a decrease in blood pressure in a large proportion of overweight people with hypertension. It has been suggested that fat distribution might be a more critical indicator of hypertension risk than actual overweight. The waist-to-hip ratio commonly is used to differentiate central or upper body obesity, with fat cells located in the abdomen and visceras, from peripheral or lower body obesity, with fat cell deposits in the buttocks and legs. Studies have found an association between hypertension and increased waist-to-hip ratio (i.e., central obesity), even when body mass index and skinfold thickness are taken into account. Abdominal or visceral fat seems to cause more insulin resistance, glucose intolerance, dyslipidemia, hypertension, and chronic kidney disease than subcutaneous fat. There is also an evolving understanding of the neuroendocrine effects of excess adipose tissue on blood pressure.

Recent evidence indicates that leptin, an adipocyte-derived hormone, may represent a link between adiposity and increased cardiovascular sympathetic activity. Besides its effect on appetite and metabolism, leptin acts on the hypothalamus to increase blood pressure through activation of the SNS. High levels of circulating free fatty acids in obese people also appear to participate in activation of the SNS. There is also research supporting activation of the renin–angiotensin–aldosterone system by adipocyte-derived angiotensinogen and the ability of adipose tissue to increase aldosterone levels through the production of factors that induce aldosterone production.

**Excess Alcohol Consumption.** Regular alcohol drinking plays a role in the development of hypertension. The effect is seen with different types of alcoholic drinks, in men and women, and in a variety of ethnic groups. The recommended safe amount of alcohol is one drink per day for women and two drinks per day for men. Moderate amounts of alcohol may reduce the risk of cardiovascular disease, but most experts do not recommend alcohol consumption. Excessive amounts of alcohol consumption for prolonged periods of time have shown to promote the development of hypertension. However, blood pressure may improve or return to normal when alcohol consumption is decreased or eliminated. The mechanism whereby alcohol exerts its effect on blood pressure is unclear. It has been suggested that lifestyle factors such as obesity and lack of exercise may be accompanying factors.

**Dietary Intake of Potassium, Calcium, and Magnesium.** Low levels of dietary potassium have also been linked to increased blood pressure. The strongest evidence comes from the previously described INTERSALT study. In this study, a 60-mmol/day or greater urinary excretion of potassium (an indirect measure of potassium intake) was associated with a reduction in systolic pressure of 3.4 mm Hg or more and a decrease in diastolic pressure of 1.9 mm Hg or more. Various mechanisms have been proposed to explain the influence of potassium on blood pressure, including a purported change in the ratio of sodium to potassium in the diet, a direct natriuretic effect, and suppression of the renin–angiotensin system. In terms of food intake, a diet high in potassium usually is low in sodium and usually consists of an increased consumption of fruits and vegetables.

The associations between high blood pressure and calcium and magnesium levels also have been investigated. Although there have been reports of high blood pressure in people with low calcium intake or lowering of blood pressure with increased calcium intake, the link between low calcium and hypertension is inconclusive. Magnesium only decreases blood pressure when magnesium levels are low before supplementation.
Obstructive Sleep Apnea. Obstructive sleep apnea (OSA) and hypertension have been correlated. There have been various studies that found increased levels of norepinephrine, endothelin and aldosterone; vascular stiffening; activation of the renin–angiotensin system; endothelial dysfunction; oxidative stress; and SNS hyperactivity.33 One study found that in a group of 41 people with resistant hypertension, 83% were diagnosed with OSA. However, it is still unclear whether OSA is an impendent risk factor or a trigger of cardiovascular disease.34

Clinical Manifestations

Target-Organ Damage. Primary (essential) hypertension is typically an asymptomatic disorder. When symptoms do occur, they are usually related to the long-term effects of hypertension on other organ systems such as the kidneys, heart, eyes, and blood vessels. The JNC 7 report uses the term target-organ damage to describe the heart, brain, peripheral vascular, kidney, and retinal complications associated with hypertension9 (Chart 31.1). The excess morbidity and mortality related to hypertension are progressive over the whole range of systolic and diastolic pressures, with target-organ damage varying markedly among people with similar levels of hypertension.

Hypertension is a major risk factor for atherosclerosis since it promotes and/or accelerates plaque formation and possible rupture. It predisposes to all major atherosclerotic cardiovascular disorders, including coronary heart disease, heart failure, stroke, and peripheral artery disease. The risk for coronary artery disease and stroke depends to a great extent on other risk factors, such as obesity, smoking, and elevated cholesterol levels as well as genetic predisposition. In clinical trials, antihypertensive therapy has been associated with reductions in stroke incidence averaging up to 44%, myocardial infarction, up to 25%, and heart failure, more than 50%.3,9,33

An elevation in blood pressure increases the workload of the left ventricle by increasing the pressure against which the heart must pump as it ejects blood into the systemic circulation.11 The pressure over time increases the workload of the heart. Over time, the left ventricular wall remodels and hypertrophies to compensate for the increased pressure work. This left ventricular hypertrophy is a major risk factor for coronary heart disease, cardiac dysrhythmias, sudden death, and congestive heart failure since it cannot pump efficiently. Hypertensive left ventricular hypertrophy regresses with certain medication therapy. Regression is most closely related to systolic pressure reduction and does not appear to reflect the particular type of medication used.

Chronic hypertension leads to nephrosclerosis, a common cause of chronic kidney disease. The damage to the kidneys is caused by multiple mechanisms. One of the major ways hypertension causes damage to the kidneys is through glomerular hypoperfusion. This hypoperfusion then causes glomerulosclerosis and tubulointerstitial fibrosis. Other ways that have been studied include endothelial dysfunction from high glomerular pressures. Hypertensive kidney disease is more common in blacks than whites. Hypertension also plays an important role in accelerating the course of other types of kidney disease, particularly diabetic nephropathy. Because of the risk for diabetic nephropathy, the American Diabetes Association recommends that people with diabetes maintain their blood pressure at levels less than 130/80 mm Hg.12

Dementia and cognitive impairment occur more commonly in persons with hypertension.9 Hypertension, particularly systolic hypertension, is a major risk factor for ischemic stroke and intracerebral hemorrhage.13 Narrowing and sclerosis of small penetrating arteries in the subcortical regions of the brain are common findings on autopsy in people with chronic hypertension.9 These changes are thought to contribute to hypoperfusion, loss of autoregulation of blood flow, and impairment of the blood–brain barrier, ultimately leading to subcortical white matter demyelination. Effective antihypertensive therapy strongly reduces the risk of development of significant white matter changes. However, existing white matter changes, once established, do not appear to be reversible.11

Hypertension also affects the eye in sometimes devastating ways. Hypertensive retinopathy affects the retina through a series of microvascular changes.36 The eye of a person with hypertension will initially have increased vasomotor tone, which causes generalized arteriolar narrowing. As hypertension persists, arteriosclerotic changes become worse and include media wall hyperplasia, intimal thickening, and hyaline degeneration. These long-term changes can cause more severe arteriovenous (AV) nicking and may cause blindness (Fig. 31.5). If there are acute increases in BP, hemorrhages, microaneurysms, and hard exudates can manifest. There have been many studies that confirm there is a strong association between hypertension retinopathy and elevated BP. This is a target organ that would need to be evaluated regularly in a person with hypertension to prevent extensive damage to the eyes.36

Diagnosis. Unlike disorders of other body systems that are diagnosed by methods such as radiography and tissue examination, hypertension and other blood pressure disorders

are determined by repeated blood pressure measurement. Laboratory tests, x-ray films, and other diagnostic tests usually are done to exclude secondary hypertension and determine the presence or extent of target-organ damage.

Blood pressure measurements should be taken when the person is relaxed and has rested for at least 5 minutes and has not smoked or ingested caffeine within 30 minutes. At least two measurements should be made at each visit in the same arm while the person is seated in a chair (rather than on the examination table) with the feet on the floor and arm supported at heart level. If the first two readings differ by more than 5 mm Hg, additional readings should be taken. Both the systolic and diastolic pressures should be recorded. The increased availability of hypertensive screening clinics provides one of the best means for early detection.

Because blood pressure in many people is highly variable, blood pressure should be measured on different occasions over a period of several months before a diagnosis of hypertension is made unless the pressure is extremely elevated or associated with symptoms. The guidelines for diagnosis of hypertension before pharmacologic intervention are discussed in the JNC 7 report. According to these guidelines, confirmation of hypertension is based on the initial visit plus one or more follow-up visits in which two blood pressure readings were recorded at each visit. A standardized measurement technique should be used when confirming an initially elevated blood pressure. The JNC 7 recommendations for follow-up of people with various stages of hypertension are included in Table 31.1.

Ambulatory Blood Pressure Measurement. As previously discussed, ambulatory and self/home measurement of blood pressure may provide valuable information outside the clinician’s office regarding the person’s blood pressure and response to treatment. Self/home measurement can help detect “white coat hypertension,” a condition in which the blood pressure is consistently elevated in the health care provider’s office but normal at other times. It can also be used to assess the response to treatment methods for hypertension, assess symptoms of hypotension while on antihypertensive medications, assess episodic hypertension, motivate adherence to treatment regimens, and potentially reduce health care costs.

Ambulatory blood pressure monitoring can also be used to determine alterations in a person’s circadian blood pressure profile. Changes in the normal circadian blood pressure profile may occur in a number of conditions, including malignant hypertension, Cushing syndrome, preeclampsia, orthostatic hypotension, congestive heart failure, and sleep apnea. There is increasing evidence that people with a nondipping pattern of hypertension are at higher risk for development of target-organ damage than those with a dipping pattern. In addition, people with an excessive morning surge in blood pressure may also be at increased risk for disease development.

Treatment. The main objective for treatment of essential hypertension is to achieve and maintain arterial blood pressure below 140/90 mm Hg, with the goal of preventing morbidity and mortality. In people with hypertension and diabetes or renal disease, the goal is below 130/80 mm Hg. The JNC 7 report contains a treatment algorithm for hypertension that includes lifestyle modification and, when necessary, guidelines for the use of pharmacologic agents to achieve and maintain blood pressure within an optimal range (Fig. 31.6).

For people with secondary hypertension, efforts are made to correct or control the disease condition causing the hypertension (see “Secondary Hypertension” for treatment specifics). Antihypertensive medications and other measures supplement the treatment of the underlying disease.

Lifestyle Modification. Lifestyle modification has been shown to reduce blood pressure, enhance the effects of antihypertensive drug therapy, and prevent cardiovascular risk. Major lifestyle modifications shown to lower blood pressure include weight reduction in persons who are overweight or obese, regular physical activity (30 minutes most days of the week), adoption of the DASH eating plan, reduction of dietary salt intake, and limitation of alcohol intake to no more than two drinks per day for most men and one drink for women and people of lighter weight (Table 31.2). Although nicotine has not been associated with long-term elevations in blood pressure as in essential hypertension, it has been shown to increase the risk for heart disease. The fact that smoking and hypertension are major cardiovascular risk factors should be reason enough to encourage the person with hypertension to quit smoking. There is conflicting evidence about the direct effects of dietary fats on blood pressure. As with smoking, the interactive effects of saturated fats and high blood pressure as cardiovascular risk factors would seem to warrant dietary modification to reduce the intake of foods high in cholesterol and saturated fats.

Pharmacologic Treatment. The decision to initiate pharmacologic treatment is based on the stage and severity of the hypertension, the presence of target-organ disease, and the existence of other disease conditions and risk factors. The JNC 7 has developed a pharmacologic treatment algorithm
for use in the pharmacologic treatment of hypertension\(^a\) (see Fig. 31.6). Among the drugs used in the treatment of hypertension are diuretics, \(\beta\)-adrenergic blocking agents, ACE inhibitors or angiotensin II receptor blockers, calcium channel blocking agents, \(\alpha_1\)-adrenergic receptor antagonists, \(\alpha_2\)-adrenergic agonists that act at the level of the central nervous system (CNS), and vasodilators.

**Diuretics**, such as the thiazides, loop diuretics, and the aldosterone antagonist (potassium-sparing) diuretics, lower blood pressure initially by decreasing vascular volume (by suppressing renal reabsorption of sodium and increasing salt and water excretion) and cardiac output. With continued therapy, a reduction in peripheral vascular resistance becomes a major mechanism of blood pressure reduction. When begun, blood pressure will fall about 10 mm Hg, depending on various factors such as initial blood pressure and adequacy of renal function. Diuretics are generally well tolerated by people and are less expensive than other antihypertensive agents.

The **\(\beta\)-adrenergic receptor blockers** are effective in treating hypertension because they decrease heart rate and cardiac output. These agents also decrease renin release, thereby decreasing the effect of the renin–angiotensin–aldosterone mechanism on blood pressure. There are several types of \(\beta\)-adrenergic receptors: \(\beta_1\) and \(\beta_2\). The \(\beta_1\)-adrenergic blocking drugs are cardioselective, exerting their effects on the heart, whereas the \(\beta_2\)-adrenergic receptor blockers affect bronchodilation, relaxation of skeletal blood vessels, and other \(\beta\)-mediated functions. Both cardioselective (targeting \(\beta_1\) receptors) and nonselective (targeting \(\beta_1\) and \(\beta_2\) receptors) \(\beta\)-adrenergic blockers are used in the treatment of hypertension, especially recommended for people who have concomitant coronary artery disease. The combined alpha and beta-blocker is also available and approved for heart failure as well.

The **ACE inhibitors** act by inhibiting the conversion of angiotensin I to angiotensin II, thus decreasing angiotensin II levels and reducing its effect on vasoconstriction, aldosterone

levels, intrarenal blood flow, and the glomerular filtration rate. They also inhibit the degradation of bradykinin and stimulate the synthesis of vasodilating prostaglandins. The ACE inhibitors are increasingly used as the initial medication in mild to moderate hypertension. Because of their effect on the renin–angiotensin system, these drugs are contraindicated in persons with renal artery stenosis, in which the renin–angiotensin mechanism functions as a compensatory mechanism to maintain adequate renal perfusion. Because they inhibit aldosterone secretion, these agents also can increase serum potassium levels and cause hyperkalemia. A relative of ACE inhibitors medications is the angiotensin II receptor blocking agents. They decrease peripheral vascular resistance by displacing A II, which makes the blockade of the renin–angiotensin mechanism more complete. Also, because they do not inhibit bradykinin degradation in the lungs, they are less likely to produce a cough, which is a common side effect of ACE inhibitors.

The *calcium channel receptor blocking drugs* inhibit the movement of calcium into cardiac and vascular smooth muscle. They are thought to reduce blood pressure by several mechanisms, including a reduction of vascular smooth muscle tone in the venous and arterial systems. Each of the different agents in this group acts in a slightly different way. Some calcium channel blockers have a direct myocardial effect that reduces the cardiac output through a decrease in cardiac contractility and heart rate; others influence venous vasoconstriction and reduce the cardiac output through a decrease in venous return; still others influence arterial vascular smooth muscle tone by inhibiting calcium transport across the cell membrane channels or the vascular response to norepinephrine or angiotensin.

The α₂-adrenergic receptor antagonists block postsynaptic α₂ receptors and reduce the effect of the SNS on the vascular smooth muscle tone of the blood vessels that regulate the peripheral vascular resistance. These drugs produce a pronounced decrease in blood pressure after the first dose; therefore, treatment is initiated with a smaller dose given at bedtime. Postdosing palpitations, headache, and nervousness may continue with chronic treatment. These agents usually are more effective when used in combination with other agents.

The *centrally acting adrenergic agonists* block sympathetic outflow from the CNS. These agents are α₂-adrenergic agonists that act in a negative-feedback manner to decrease sympathetic outflow from presynaptic sympathetic neurons in the CNS. The α₂-adrenergic agonists are effective as a single therapy for some people, but often are used as second- or third-line agents because of the high incidence of side effects associated with their use. One of the agents, clonidine, is available as a transdermal patch that is replaced weekly.

The *direct-acting smooth muscle vasodilators* promote a decrease in peripheral vascular resistance by producing relaxation of vascular smooth muscle, particularly of the arterioles. These drugs often produce tachycardia because of an initial stimulation of the SNS, and salt and water retention owing to decreased filling of the vascular compartment. Vasodilators are most effective when used in combination with other anti-hypertensive drugs that oppose the compensatory cardiovascular responses.

**Treatment Strategies.** Factors to be considered when hypertensive drugs are prescribed are the person’s lifestyle (i.e., someone with a busy schedule may have problems with medications that must be taken two or three times each day); demographics (e.g., some drugs are more effective in elderly or black people); motivation for adhering to the drug regimen (e.g., some drugs can produce undesirable and even
life-threatening consequences if discontinued abruptly; other disease conditions and therapies (beta-blocker for a person with coronary artery disease); and potential for side effects (e.g., some drugs may impair sexual functioning or mental acuity; others have not been proved safe for women of childbearing age). Particular caution should be used in people who are at risk for orthostatic hypotension (e.g., those with diabetes, ANS dysfunction, and some older adults). Another factor to be considered is the cost of the drug in relation to financial resources. There is wide variation in the prices of antihypertensive medications, and this factor should be considered when medications are prescribed. This is particularly important for low-income people with moderate to severe hypertension because keeping costs at an affordable level may be the key to compliance.\(^9\)

**Secondary Hypertension**

Secondary hypertension, which describes an elevation in blood pressure due to another disease condition, accounts for 5% to 10% of hypertension cases.\(^{38}\) Unlike primary hypertension, many of the conditions causing secondary hypertension can be corrected or cured by surgery or specific medical treatment. Secondary hypertension tends to be seen in people younger than 30 and older than 50 years of age. Cocaine, amphetamines, and other illicit drugs can cause significant hypertension, as can sympathomimetic agents (decongestants, anorectics), erythropoietin, and licorice (including some chewing tobaccos with licorice as an ingredient).

Among the most common causes of secondary hypertension are kidney disease (i.e., renovascular hypertension), adrenal cortical disorders, pheochromocytoma, and coarctation of the aorta. To avoid duplication in descriptions, the mechanisms associated with elevations of blood pressure in these disorders are discussed briefly, and a more detailed discussion of specific disease disorders is reserved for other sections of this book. Oral contraceptive agents are also implicated as a cause of secondary hypertension.

**Renal Hypertension**

With the dominant role that the kidney assumes in blood pressure regulation, it is not surprising that the largest single cause of secondary hypertension is renal disease. Most acute kidney disorders result in decreased urine formation, retention of salt and water, and hypertension. This includes acute glomerulonephritis, acute renal failure, and acute urinary tract obstruction. Hypertension also is common among people with chronic pyelonephritis, polycystic kidney disease, diabetic nephropathy, and end-stage renal disease, regardless of cause. In older adults, the sudden onset of secondary hypertension often is associated with atherosclerotic disease of the renal blood vessels.

Renovascular hypertension refers to hypertension caused by reduced renal blood flow and activation of the renin–angiotensin–aldosterone mechanism. It is the most common cause of secondary hypertension, accounting for 1% to 2% of all cases of hypertension.\(^{11}\) The reduced renal blood flow that occurs with renovascular disease causes the affected kidney to release excessive amounts of renin, increasing circulating levels of angiotensin II. Angiotensin II, in turn, acts as a vasoconstrictor to increase peripheral vascular resistance and as a stimulus for increased aldosterone levels and sodium retention by the kidney. One or both of the kidneys may be affected. When the renal artery of only one kidney is involved, the unaffected kidney is subjected to the detrimental effects of the elevated blood pressure.

There are two major types of renovascular disease—atherosclerosis of the proximal renal artery and fibromuscular dysplasia, a noninflammatory vascular disease that affects the renal arteries and branch vessels.\(^{13,39,40}\) Atherosclerotic stenosis of the renal artery accounts for 70% to 90% of cases and is seen most often in older adults, particularly

---

**KEY POINTS**

**HYPERTENSION**

- Hypertension represents an elevation in systolic and/or diastolic blood pressure.
- Essential hypertension is characterized by a chronic elevation in blood pressure that occurs without evidence of other disease, and secondary hypertension by an elevation of blood pressure that results from some other disorder, such as kidney disease.

**Systolic Hypertension**

The JNC 7 report defined systolic hypertension as a systolic pressure of 140 mm Hg or greater and a diastolic pressure of less than 90 mm Hg, indicating a need for increased recognition and control of isolated systolic hypertension.\(^9\) Historically, diastolic hypertension was thought to confer a greater risk for cardiovascular events than systolic hypertension.\(^9\) However, there is mounting evidence that elevated systolic blood pressure is at least as important, if not more so, than diastolic hypertension.\(^{37}\)

There are two aspects of systolic hypertension that confer increased risk for cardiovascular events. One is the actual elevation in systolic pressure and the other is the disproportionate rise in pulse pressure. Elevated pressures during systole favor the development of left ventricular hypertrophy, increased myocardial oxygen demands, and eventual left heart failure. At the same time, the absolute or relative lowering of diastolic pressure is a limiting factor in coronary perfusion because coronary perfusion is greatest during diastole. Elevated pulse pressures produce greater stretch of arteries, causing damage to the elastic elements of the vessel and thus predisposing to aneurysms and development of the intimal damage that leads to atherosclerosis and thrombosis.\(^{37}\)
those with diabetes, aortoiliac occlusive disease, coronary artery disease, or hypertension. Fibromuscular dysplasia is more common in women and tends to occur in younger age groups, often people in their third decade. Genetic factors may be involved, and the incidence tends to increase with risk factors such as smoking and hyperlipidemia.

Renal artery stenosis should be suspected when hypertension develops in a previously normotensive person older than 50 (i.e., atherosclerotic form) or younger than 30 (i.e., fibromuscular dysplasia) years of age, or when accelerated hypertension occurs in a person with previously controlled hypertension. Hypokalemia (due to increased aldosterone levels), the presence of an abdominal bruit, the absence of a family history of hypertension, and a duration of hypertension of less than 1 year help to distinguish renovascular hypertension from essential hypertension. Because renal blood flow depends on the increased blood pressure generated by the renin–angiotensin system, administration of ACE inhibitors can cause a rapid decline in renal function.

Diagnostic tests for renovascular hypertension may include studies to assess overall renal function, physiologic studies to assess the renin–angiotensin system, perfusion studies to evaluate renal blood flow, and imaging studies to identify renal artery stenosis. Renal arteriography remains the definitive test for identifying renal artery disease. Duplex ultrasonographic scanning, contrast-enhanced computed tomography (CT), and magnetic resonance angiography (MRA) are other tests that can be used to screen for renovascular hypertension.

The goal of treatment of renal hypertension is to control the blood pressure and stabilize renal function. Angioplasty or revascularization has been shown to be an effective long-term treatment for the disorder. ACE inhibitors may be used in medical management of renal stenosis. However, these agents must be used with caution because of their ability to produce marked hypotension and renal dysfunction.

**Disorders of Adrenocortical Hormones**

Increased levels of adrenocortical hormones also can give rise to hypertension. Primary hyperaldosteronism (excess production of aldosterone due to adrenocortical hyperplasia or adenoma) and excess levels of glucocorticoid (Cushing disease or syndrome) tend to raise the blood pressure. In fact hypertension occurs in 80% of people with Cushing syndrome. These hormones facilitate salt and water retention by the kidney. The hypertension that accompanies excessive levels of either hormone probably is related to this factor. For people with primary hyperaldosteronism, a salt-restricted diet often produces a reduction in blood pressure. Because aldosterone acts on the distal renal tubule to increase sodium absorption in exchange for potassium elimination in the urine, people with hyperaldosteronism usually have decreased potassium levels. Screening tests for primary hyperaldosteronism involve the determination of plasma aldosterone concentration and plasma renin activity. CT and MRI scans are used to localize the lesion. People with solitary adenomas are usually treated surgically.

Potassium-sparing diuretics, such as spironolactone, which is an aldosterone antagonist, often are used in the medical management of people with bilateral hyperplasia.

**Pheochromocytoma**

A pheochromocytoma is a tumor of chromaffin tissue, which contains sympathetic nerve cells that stain with chromium salts and release catecholamine. The tumor is most commonly located in the adrenal medulla but can arise in other sites, such as the sympathetic ganglia, where there is chromaffin tissue. Although only 0.1% to 0.5% of people with hypertension have an underlying pheochromocytoma, the disorder can cause serious hypertensive crises.

Like adrenal medullary cells, the tumor cells of a pheochromocytoma produce and secrete the catecholamines epinephrine and norepinephrine. The hypertension that develops is a result of the massive release of these catecholamines. Their release may be paroxysmal rather than continuous, causing periodic episodes of headache, excessive sweating, and palpitations. Headache is the most common symptom and can be quite severe. Nervousness, tremor, facial pallor, weakness, fatigue, and weight loss occur less frequently. Marked variability in blood pressure between episodes is typical. Approximately 50% of people with pheochromocytoma have paroxysmal episodes of hypertension, sometimes to dangerously high levels. The other 50% have sustained hypertension, and some even may be normotensive.

Several tests are available to differentiate hypertension due to pheochromocytoma from other forms of hypertension. The most commonly used diagnostic measure is the determination of urinary catecholamines and their metabolites. Although measurement of plasma catecholamines also may be used, other conditions can cause catecholamines to be elevated. After the presence of a pheochromocytoma has been established, the tumor needs to be located. MRI and CT scans may be used for this purpose. Radioisotopes that localize the chromaffin tissue are available. Surgical endoscopic removal of operable tumors is usually curative. If the tumor is not resectable, treatment with drugs that block the action or synthesis of catecholamines can be used.

**Coarctation of the Aorta**

Coarctation represents a narrowing of the aorta. In the adult form of aortic coarctation, the narrowing most commonly occurs just distal to the origin of the subclavian arteries. Because of the narrowing, blood flow to the lower parts of the body and kidneys is reduced. In the infantile form of coarctation, the narrowing occurs proximal to the ductus arteriosus, in which case heart failure and other problems may occur. Many affected infants die within their first year of life.

In the adult form of aortic coarctation, the ejection of an increased stroke volume into a narrowed aorta causes an increase in systolic blood pressure and blood flow to the upper part of the body. Blood pressure in the lower extremities may be normal, although it frequently is low. It has been suggested that the increase in stroke volume and maintenance of the
pressure to the lower part of the body is achieved through the renin–angiotensin–aldosterone mechanism in response to a decrease in renal blood flow. Pulse pressure in the legs almost always is narrowed, and the femoral pulses are weak. Because the aortic capacity is diminished, there usually is a marked increase in pressure (measured in the arms) during exercise, when the stroke volume and heart rate are increased. For this reason, blood pressures in both arms and one leg should be determined; a pressure that is 20 mm Hg more in the arms than in the legs suggests coarctation of the aorta. Involvement of the left subclavian artery or an anomalous origin of the right subclavian may produce decreased or absent left or right brachial pulses, respectively. Palpation of both brachial pulses and measurement of blood pressure in both arms are important.

Treatment consists of surgical repair or balloon angioplasty. Although balloon angioplasty is a relatively recent form of treatment, it has been used in children and adults with good results. Long-term follow-up is required for monitoring of hypertension. However, there are few data on long-term follow-up.

**Oral Contraceptive Drugs**

The use of oral contraceptive pills is probably the most common cause of secondary hypertension in young women. Women taking oral contraceptive should have their blood pressure taken regularly. The Nurses Health Study (a prospective cohort study of over 70,000 nurses over 4 years between 1989 and 1993) found that current users of oral contraceptives had a significant, moderately increased risk of hypertension. However, among this group, only 41.5 cases per 10,000 person-years could be attributed to oral contraceptive use.

The cause of the increased blood pressure is largely unknown, although it has been suggested that the probable cause is volume expansion because both estrogen and synthetic progesterones used in oral contraceptive pills cause sodium retention. Various contraceptive drugs contain different amounts and combinations of estrogen and prostaglandin agents, and these differences may contribute to the occurrence of hypertension in some women but not others. Fortunately, the hypertension associated with oral contraceptives usually disappears after the drug has been discontinued, although it may take as long as 3 months for this to happen. However, in some women, the blood pressure may not return to normal, and they may be at risk for development of hypertension. The risk for hypertension-associated cardiovascular complications is found primarily in women older than 35 years of age and in those who smoke.

**Malignant Hypertension**

A small number of people with hypertension develop an accelerated and potentially fatal form of the disease termed malignant hypertension. This usually is a disease of younger people, particularly young black men, women with toxemia of pregnancy, and people with renal and collagen diseases.

Malignant hypertension is characterized by sudden, marked elevations in blood pressure, with diastolic values above 120 mm Hg complicated by evidence of acute or rapidly progressive life-threatening organ dysfunction. There may be intense arterial spasm of the cerebral arteries with hypertensive encephalopathy. Cerebral vasospasm is probably an exaggerated homeostatic response designed to protect the brain from excesses of blood pressure and flow. The regulatory mechanisms often are insufficient to protect the capillaries, and cerebral edema frequently develops. As it advances, papilledema (i.e., swelling of the optic nerve at its point of entrance into the eye) ensues, giving evidence of the effects of pressure on the optic nerve and retinal vessels. The person may have headache, restlessness, confusion, stupor, motor and sensory deficits, and visual disturbances. In severe cases, convulsions and coma follow.

Prolonged and severe exposure to exaggerated levels of blood pressure in malignant hypertension injures the walls of the arterioles, and intravascular coagulation and fragmentation of red blood cells may occur. The renal blood vessels are particularly vulnerable to hypertensive damage. Renal damage due to vascular changes probably is the most important prognostic determinant in malignant hypertension. Elevated levels of blood urea nitrogen and serum creatinine, metabolic acidosis, hypocalcemia, and proteinuria provide evidence of renal impairment.

The complications associated with a hypertensive crisis demand immediate and rigorous medical treatment in an intensive care unit with continuous monitoring of arterial blood pressure. With proper therapy, the death rate from this cause can be markedly reduced, as can complications and additional episodes. Because chronic hypertension is associated with autoregulatory changes in coronary artery, cerebral artery, and kidney blood flow, care should be taken to avoid excessively rapid decreases in blood pressure, which can lead to hypoperfusion and ischemic injury. Therefore, the goal of initial treatment measures should be to obtain a partial reduction in blood pressure to a safer, less critical level, rather than to normotensive levels.

**High Blood Pressure in Pregnancy**

Hypertensive disorders of pregnancy complicate 5% to 10% of pregnancies and remain a major cause of maternal and neonatal mortality and morbidity in the United States and worldwide. Most adverse events are attributable directly to the preeclampsia syndrome, characterized by new-onset hypertension with proteinuria that develops after 20 weeks of pregnancy. Women with chronic hypertension can also manifest adverse events.

**Etiology and Pathogenesis**

Defining the cause or causes of hypertension that occurs during pregnancy is difficult because of the normal circulatory changes that occur. Blood pressure normally decreases during the first trimester, reaches its lowest point during the second trimester,
and gradually rises during the third trimester. The fact that there is a large increase in cardiac output during early pregnancy suggests that the decrease in blood pressure that occurs during the first part of pregnancy results from a decrease in peripheral vascular resistance. Because the cardiac output remains high throughout pregnancy, the gradual rise in blood pressure that begins during the second trimester probably represents a return of the peripheral vascular resistance to normal.\(^{13}\) Pregnancy normally is accompanied by increased levels of renin, angiotensin I and II, estrogen, progesterone, prolactin, and aldosterone, all of which may alter vascular reactivity. Women who experience preeclampsia are thought to be particularly sensitive to the vasoconstrictor activity of the renin–angiotensin–aldosterone system. They also are particularly responsive to other vasoconstrictors, including the catecholamines and vasopressin. It has been proposed that some of the sensitivity may be caused by a prostaglandin–thromboxane imbalance. Thromboxane is a prostaglandin with vasoconstrictor properties, and prostacyclin is a prostaglandin with vasodilator properties. Emerging evidence suggests that insulin resistance, including that which occurs with diabetes, obesity, and the metabolic syndrome, may predispose to the hypertensive disorders of pregnancy.

**Classification**

In 2000, the National Institutes of Health Working Group on High Blood Pressure in Pregnancy published a revised classification system for high blood pressure in pregnancy that included preeclampsia–eclampsia, gestational hypertension, chronic hypertension, and preeclampsia superimposed on chronic hypertension\(^{13}\) (Table 31.3).

**Preeclampsia–Eclampsia.** Preeclampsia–eclampsia is a pregnancy-specific syndrome with both maternal and fetal manifestations.\(^ {3,44}\) It is defined as an elevation in blood pressure (systolic blood pressure >140 mm Hg or diastolic pressure >90 mm Hg) and proteinuria (≥300 mg in 24 hours) developing after 20 weeks of gestation. The Working Group recommends that K5 be used for determining diastolic pressure. Edema, which previously was included in definitions of preeclampsia, was excluded from this most recent definition. The presence of a systolic blood pressure of 160 mm Hg or higher or a diastolic pressure of 110 mm Hg or higher, proteinuria greater than 2 g in 24 hours, serum creatinine greater than 1.2 mg/dL, platelet counts less than 100,000 cells/mm\(^3\); elevated liver enzymes (alanine aminotransferase [ALT] or aspartate aminotransferase [AST]), persistent headache or cerebral or visual disturbances, and persistent epigastric pain serves to reinforce the diagnosis.\(^ {44}\) In a woman with preeclampsia, eclampsia is the occurrence of seizures that cannot be attributed to other causes.\(^ {44}\)

Preeclampsia occurs primarily during first pregnancies and during subsequent pregnancies in women with multiple fetuses, diabetes mellitus, collagen vascular disease, or underlying kidney disease.\(^ {13}\) It is also associated with a condition called a hydatidiform mole (i.e., abnormal pregnancy caused by a pathologic ovum, resulting in a mass of cysts). Women with chronic hypertension who become pregnant have an increased risk for preeclampsia and adverse neonatal outcomes, particularly when associated with proteinuria early in pregnancy.

The cause of pregnancy-induced hypertension is largely unknown. Considerable evidence suggests that the placenta is the key factor in all the manifestations because delivery is the only definitive cure for this disease. Pregnancy-induced hypertension is thought to involve a decrease in placental blood flow leading to the release of toxic mediators that alter the function of endothelial cells in blood vessels throughout the body, including those of the kidney, brain, liver, and heart.\(^ {13,43}\) The endothelial changes result in signs and symptoms of preeclampsia and, in more severe cases, of intravascular clotting and hypoperfusion of vital organs. There is risk for development of disseminated intravascular coagulation (DIC), cerebral hemorrhage, hepatic failure, and acute renal failure. Thrombocytopenia is the most common hematologic

| TABLE 31.3 CLASSIFICATION OF HIGH BLOOD PRESSURE IN PREGNANCY |
|-----------------|---------------------------------------------------------------|
| **CLASSIFICATION** | **DESCRIPTION** |
| Preeclampsia–eclampsia | Pregnancy-specific syndrome of blood pressure elevation (blood pressure >140 mm Hg systolic or >90 mm Hg diastolic) that occurs after the first 20 weeks of pregnancy and is accompanied by proteinuria (urinary excretion of 0.3 g protein in a 24-hour specimen). |
| Gestational hypertension | Blood pressure elevation, without proteinuria, that is detected for the first time during mid-pregnancy and returns to normal by 12 weeks postpartum. |
| Chronic hypertension | Blood pressure ≥140 mm Hg systolic or ≥90 mm Hg diastolic that is present and observable before the 20th week of pregnancy. Hypertension that is diagnosed for the first time during pregnancy and does not resolve after pregnancy also is classified as chronic hypertension. |
| Preeclampsia superimposed on chronic hypertension | Chronic hypertension (blood pressure ≥140 mm Hg systolic or ≥90 mm Hg diastolic before the 20th week of pregnancy) with superimposed proteinuria and with or without signs of the preeclampsia syndrome. |

complication of preeclampsia. Platelet counts of less than 100,000/mm³ signal serious disease. The cause of thrombocytopenia has been ascribed to platelet deposition at the site of endothelial injury. The renal changes that occur with preeclampsia include a decrease in glomerular filtration rate and renal blood flow. Sodium excretion may be impaired, although this is variable. Edema may or may not be present. Some of the severest forms of preeclampsia occur in the absence of edema. Even when there is extensive edema, the plasma volume usually is lower than that of a normal pregnancy. Liver damage, when it occurs, may range from mild hepatocellular necrosis with elevation of liver enzymes to the more ominous hemolysis, elevated liver function test results, and low platelet count (HELLP) syndrome that is associated with significant maternal mortality. Eclampsia, the convulsive stage of preeclampsia, is a significant cause of maternal mortality. The pathogenesis of eclampsia remains unclear but has been attributed to both increased blood coagulability and fibrin deposition in the cerebral vessels.

The decreased placental blood flow that occurs with preeclampsia also affects the fetus. It frequently results in intrauterine growth restriction and infants who are small for gestational age. Preeclampsia is one of the leading causes of prematurity because of frequent need for early delivery in affected women.

Gestational Hypertension. Gestational hypertension represents a blood pressure elevation greater than 140/90 on two separate occasions without proteinuria that is detected for the first time after 20 weeks. It includes women with preeclampsia syndrome who have not yet manifested proteinuria as well as women who do not have the syndrome. Other signs of the preeclampsia syndrome may accompany the hypertension. The final determination that a woman does not have the preeclampsia syndrome is made only postpartum. If preeclampsia has not developed and blood pressure has returned to normal by 12 weeks postpartum, the condition is considered to be gestational hypertension. If blood pressure elevation persists, a diagnosis of chronic hypertension is made.

Chronic Hypertension. Chronic hypertension is considered to be hypertension that is unrelated to the pregnancy. It is defined as a history of high blood pressure before pregnancy (BP > 140/90), identification of hypertension before 20 weeks of pregnancy, and hypertension that persists after pregnancy. Hypertension that is diagnosed for the first time during pregnancy and does not resolve after pregnancy also is classified as chronic hypertension. In women with chronic hypertension, blood pressure often decreases in early pregnancy and increases during the last trimester (3 months) of pregnancy, resembling preeclampsia. Consequently, women with undiagnosed chronic hypertension who do not present for medical care until the later months of pregnancy may be incorrectly diagnosed as having preeclampsia.

Preeclampsia Superimposed on Chronic Hypertension. Women with chronic hypertension are at increased risk for the development of preeclampsia, in which case the prognosis for the mother and fetus tends to be worse than for either condition alone. Superimposed preeclampsia should be considered in women with hypertension before 20 weeks of gestation who develop new-onset proteinuria, women with hypertension and proteinuria before 20 weeks of gestation, women with previously well-controlled hypertension who experience a sudden increase in blood pressure, and women with chronic hypertension who develop thrombocytopenia or an increase in serum ALT or AST to abnormal levels.

Diagnosis and Treatment

Early prenatal care is important in the detection of high blood pressure during pregnancy. It is recommended that all pregnant women, including those with hypertension, refrain from alcohol and tobacco use. Salt restriction usually is not recommended during pregnancy because pregnant women with hypertension tend to have lower plasma volumes than normotensive pregnant women and because the severity of hypertension may reflect the degree of volume contraction. The exception is women with preexisting hypertension who have been following a salt-restricted diet.

In women with preeclampsia, delivery of the fetus is curative. The timing of delivery becomes a difficult decision in preterm pregnancies because the welfare of both the mother and the infant must be taken into account. Bed rest is a traditional therapy. Antihypertensive medications, when required, must be carefully chosen because of their potential effects on uteroplacental blood flow and on the fetus. For example, the ACE inhibitors can cause injury and even death of the fetus when given during the second and third trimesters of pregnancy.

High Blood Pressure in Children and Adolescents

Until recently, the incidence of hypertension among children has been low, with a range of 1% to 3%. Recent data, however, indicate that the prevalence and rate of diagnosis of hypertension in children and adolescents appear to be increasing. This may be due in part to increasing prevalence of obesity and other lifestyle factors, such as decreased physical activity and increased intake of high-calorie, high-salt foods. Secondary hypertension is the most common form of high blood pressure in infants and children. In later childhood and adolescence, essential hypertension is more common.

Blood pressure is known to increase from infancy to late adolescence. The average systolic pressure at 1 day of age is approximately 70 mm Hg and increases to approximately 85 mm Hg at 1 month of age. Systolic blood pressure continues to increase with physical growth to about 120 mm Hg at the end of adolescence. During the preschool years, blood pressure begins to follow a pattern that tends to be maintained as the child grows older. This pattern continues into adolescence and adulthood, suggesting that the roots of essential
hypertension have their origin early in life. A familial influence on blood pressure often can be identified early in life. Children of parents with high blood pressure tend to have higher blood pressures than do children with normotensive parents.

Blood pressure norms for children are based on age-, height-, and sex-specific percentiles\(^47\) (Table 31.4). The National High Blood Pressure Education Program (NHBPEP) first published its recommendations in 1977. The fourth Task Force report (published in 2004) recommended classification of blood pressure (systolic or diastolic) for age, height, and gender into four categories:

- Normal (less than the 90th percentile).
- High normal (between the 90th and 95th percentiles).
- Stage 1 hypertension (between the 95th and 99th percentiles plus 5 mm Hg).
- Stage 2 hypertension (greater than the 99th percentile plus 5 mm Hg).\(^47\)

The height percentile is determined by using the revised CDC growth charts. Blood pressure levels are based on new data from the 1999–2000 National Health and Nutritional Examination Survey (NHANES) that have been added to the childhood BP database.

</table>

The height percentile is determined by using the newly revised CDC growth charts. Blood pressure levels are based on new data from the 1999–2000 National Health and Nutritional Examination Survey (NHANES) that have been added to the childhood BP database.

Etiology and Pathogenesis

Approximately 75% to 80% of secondary hypertension in children is caused by kidney abnormalities.\(^46\) Coarctation of the aorta is another cause of secondary hypertension in children and adolescents. Endocrine causes of hypertension, such as pheochromocytoma and adrenal cortical disorders, are rare. Hypertension in infants is associated most commonly with high umbilical catheterization and renal artery obstruction caused by thrombosis.\(^46\) Most cases of essential hypertension are associated with obesity or a family history of hypertension.
A number of drugs of abuse, therapeutic agents, and toxins also may increase blood pressure. Alcohol should be considered as a risk factor in adolescents. Oral contraceptives may be a cause of hypertension in adolescent girls. The nephrotoxicity of the drug cyclosporine, an immunosuppressant used in transplant therapy, may cause hypertension in children (and adults) after bone marrow, heart, kidney, or liver transplantation. The coadministration of corticosteroid drugs appears to increase the incidence of hypertension.

**Diagnosis and Treatment**

The Task Force recommended that children 3 years of age through adolescence should have their blood pressure taken once each year. The auscultatory method using a cuff of an appropriate size for the child’s upper arm is recommended. Repeated measurements over time, rather than a single isolated determination, are required to establish consistent and significant observations. Children with high blood pressure should be referred for medical evaluation and treatment as indicated.

Treatment includes nonpharmacologic methods and, if necessary, pharmacologic therapy. Indications for antihypertensive medication in children and adolescents include symptomatic hypertension, secondary hypertension, high-risk children (including children who have diabetes mellitus, or evidence of end organ damage).

**High Blood Pressure in Older Adults**

The prevalence of hypertension increases with advancing age to the extent that half of people aged 60 to 69 years and approximately three fourths of people 70 years and older are affected. The age-related rise in systolic blood pressure is primarily responsible for the increase in hypertension that occurs with increasing age. Isolated systolic hypertension (systolic pressure ≥140 mm Hg and diastolic pressure <90 mm Hg) is recognized as an important risk factor for cardiovascular morbidity and mortality in older adults.

**Etiology and Pathogenesis**

Among the aging processes that contribute to an increase in blood pressure are a stiffening of the large arteries, particularly the aorta; decreased baroreceptor sensitivity; increased peripheral vascular resistance; and decreased renal blood flow. Systolic blood pressure rises almost linearly between 30 and 84 years of age, whereas diastolic pressure rises until 50 years of age and then levels off or decreases. This rise in systolic pressure is thought to be related to increased stiffness of the large arteries. With aging, the elastin fibers in the walls of the arteries are gradually replaced by collagen fibers that render the vessels stiffer and less compliant. Differences in the central and peripheral arteries relate to the fact that the larger vessels contain more elastin, whereas the peripheral resistance vessels have more smooth muscle and less elastin. Because of increased wall stiffness, the aorta and large arteries are less able to buffer the increase in systolic pressure that occurs as blood is ejected from the left heart, and they are less able to store the energy needed to maintain the diastolic pressure. As a result, the systolic pressure increases, the diastolic pressure remains unchanged or actually decreases, and the pulse pressure or difference between the systolic pressure and diastolic pressure widens.

**Diagnosis and Treatment**

The recommendations for measurement of blood pressure in older adults are similar to those for the rest of the population. Blood pressure variability is particularly prevalent among older adults, so it is especially important to obtain multiple measurements on different occasions to establish a diagnosis of hypertension. The effects of food, position, and other environmental factors also are exaggerated in older adults. Although sitting has been the standard position for blood pressure measurement, it is recommended that blood pressure also be taken in the supine and standing positions in the elderly. In some older adults with hypertension, a silent interval, called the auscultatory gap, may occur between the end of the first and beginning of the third phases of the Korotkoff sounds, providing the potential for underestimating the systolic pressure, sometimes by as much as 50 mm Hg. Because the gap occurs only with auscultation, it is recommended that a preliminary determination of systolic blood pressure be made by palpation and the cuff be inflated 30 mm Hg above this value for auscultatory measurement of blood pressure. In some older adults, the indirect measurement using a blood pressure cuff and the Korotkoff sounds has been shown to give falsely elevated readings compared with the direct intra-arterial method. This is because excessive cuff pressure is needed to compress the rigid vessels of some older persons. Pseudohypertension should be suspected in older adults with hypertension in whom the radial or brachial artery remains palpable but pulseless at higher cuff pressures.

The treatment of hypertension in older adults has beneficial effects in terms of reducing the incidence of cardiovascular events such as stroke. Studies have shown a reduction in stroke, coronary heart disease, and congestive heart failure in people who were treated for hypertension compared with those who were not.

The JNC 7 recommendations for treating hypertension in older adults are similar to those for the general population. However, blood pressure should be reduced slowly and cautiously. When possible, appropriate lifestyle modifications should be tried first. Antihypertensive medications should be prescribed carefully because the older adult may have impaired baroreflex sensitivity and renal function. Usually, medications are initiated at smaller doses, and doses are increased more gradually. There is also the danger of adverse drug interactions in older adults who may be taking multiple medications, including over-the-counter drugs.

**IN SUMMARY**

Hypertension (systolic pressure ≥140 mm Hg and/or diastolic pressure ≥90 mm Hg) is one of the most common cardiovascular disorders. It may occur as a primary disorder (i.e., essential hypertension) or as a symptom of some other disease (i.e., secondary hypertension). The incidence of
essential hypertension increases with age; the condition is seen more frequently among blacks, and it may be associated with a family history of high blood pressure, metabolic syndrome, obesity, and increased sodium intake. Causes of secondary hypertension include kidney disease and adrenal cortical disorders (hyperaldosteronism and Cushing disease), which increase sodium and water retention; pheochromocytomas, which increase catecholamine levels; and coarctation of the aorta, which produces an increase in blood flow and systolic blood pressure in the arms and a decrease in blood flow and systolic pressure in the legs.

Unlike disorders of other body systems that are diagnosed by methods such as radiography and tissue examination, hypertension and other blood pressure disorders are determined by repeated blood pressure measurements. Uncontrolled hypertension increases the risk of heart disease, renal complications, retinopathy, and stroke. Treatment of essential hypertension focuses on nonpharmacologic methods such as weight reduction, reduction of sodium intake, regular physical activity, and modification of alcohol intake. Among the drugs used in the treatment of hypertension are diuretics, \( \beta \)-adrenergic blocking agents, ACE inhibitors, calcium channel blocking agents, \( \alpha_1 \)-adrenergic blocking agents, centrally acting \( \alpha_1 \) agonists, and vasodilating drugs.

Hypertension that occurs during pregnancy can be divided into four categories: preeclampsia–eclampsia, gestational hypertension, chronic hypertension, and preeclampsia superimposed on chronic hypertension. Preeclampsia–eclampsia is hypertension that develops after 20 weeks of gestation and is accompanied by proteinuria. This form of hypertension, which is thought to result from impaired placental perfusion along with the release of toxic vasoactive substances that alter blood vessel tone and blood clotting mechanisms, poses a particular threat to the mother and the fetus. Gestational hypertension represents a blood pressure elevation without proteinuria that is detected for the first time after mid-pregnancy and returns to normal by 12 weeks postpartum. Chronic hypertension is hypertension that is unrelated to the pregnancy. It is characterized by hypertension that was present before pregnancy or identified before the 20th week of pregnancy and persists after pregnancy.

The prevalence of hypertension in children and adolescents appears to be increasing, partly as a result of an increase in childhood obesity, and lifestyle factors such as physical inactivity and increased intake of high-calorie and high-salt foods. During childhood, blood pressure is influenced by growth and maturation. Therefore, blood pressure norms have been established using percentiles specific to age, height, and sex to identify children for further follow-up and treatment. Although hypertension occurs infrequently in children, it is recommended that children 3 years of age through adolescence should have their blood pressure taken once each year.

The most common type of hypertension in older adults is isolated systolic hypertension (systolic pressure \( \geq 140 \) mm Hg and diastolic pressure \(< 90 \) mm Hg). Its pathogenesis is related to the loss of elastin fibers in the aorta and the inability of the aorta to stretch during systole. Untreated systolic hypertension is recognized as an important risk factor for stroke and other cardiovascular morbidity and mortality in older adults.

ORTHOSTATIC HYPOTENSION

After completing this section of the chapter, you should be able to meet the following objectives:

- Define the term orthostatic hypotension.
- Describe the cardiovascular, neurohumoral, and muscular responses that serve to maintain blood pressure when moving from the supine to standing position.
- Explain how fluid deficit, medications, aging, disorders of the ANS, and bed rest contribute to the development of orthostatic hypotension.

Orthostatic or postural hypotension, which is a physical finding and not a disease, is an abnormal drop in blood pressure on assumption of the standing position.\(^{13,31}\) In 1995, the Joint Consensus Committee of the American Autonomic Society and the American Academy of Neurology defined orthostatic hypotension as a drop in systolic pressure of 20 mm Hg or more or a drop in diastolic blood pressure of 10 mm Hg or more within 3 minutes of standing.\(^{52}\) Although this is now the accepted definition, it does not take into account the possibility that different blood pressure declines may be symptomatic or asymptomatic, depending on the resting supine pressure. It also does not account for blood pressure changes that occur after 3 minutes of standing. Therefore, some authorities regard the presence of orthostatic symptoms (e.g., dizziness, syncope) as being more relevant than the numeric decrease in blood pressure.\(^{53}\)

Pathogenesis

After the assumption of the upright posture from the supine position, approximately 500 to 700 mL of blood is momentarily shifted to the lower part of the body, with an accompanying decrease in central blood volume and arterial pressure.\(^{13}\) Maintenance of blood pressure during position change is quite complex, involving the rapid initiation of cardiovascular, neurohumoral, and muscular responses. When the standing position is assumed in the absence of normal circulatory reflexes or blood volume, blood pools in the lower part of the body, cardiac output falls, blood pressure drops, and blood flow to the brain is inadequate. As a result, symptoms of decreased blood flow to the CNS may occur, including feelings of weakness, nausea, light-headedness, dizziness, blurred vision, palpitations, and syncope (i.e., fainting).
The decrease in blood pressure that occurs on standing is usually transient, lasting through several cardiac cycles. Normally, the baroreceptors located in the thorax and carotid sinus area sense the decreased pressure and initiate reflex constriction of the veins and arterioles and an increase in heart rate, which brings blood pressure back to normal. The initial adjustment to orthostatic stress is mediated exclusively by the ANS. Within a few minutes of standing, blood levels of ADH and sympathetic neuromediators increase as a secondary means of ensuring maintenance of normal blood pressure in the standing position. Under normal conditions, the renin–angiotensin–aldosterone system is also activated when the standing position is assumed, and even more so in situations of hypotensive orthostatic stress.

Muscle movement in the lower extremities also aids venous return to the heart by pumping blood out of the legs. The unconscious slight body and leg movement during standing (postural sway) is recognized as an important factor in moving venous blood back to the heart.11 Crossing the legs, which involves contraction of the agonist and antagonist muscles, has been shown to be a simple and effective way of increasing cardiac output and, therefore, blood pressure.

### Etiology

A wide variety of conditions, acute and chronic, are associated with orthostatic hypotension. Although orthostatic hypotension can occur in all age groups, it is seen more frequently in older adults, especially in those who are sick and frail. Any disease condition that reduces blood volume, impairs mobility, results in prolonged inactivity, or impairs ANS function may also predispose to orthostatic hypotension. Adverse effects of medications are also commonly encountered causes of orthostatic hypotension, such as diuretics.53

### Aging

Weakness and dizziness on standing are common complaints of older adults. Although orthostatic tolerance is well maintained in the healthy elderly, after 70 years of age there is an increasing tendency toward arterial pressure instability and postural hypotension. Although orthostatic hypotension may be either systolic or diastolic, that associated with aging seems more often to be systolic. Several deficiencies in the circulatory response may predispose to this problem in older adults, including diminished ability to produce an adequate increase in the heart rate, ventricular stroke volume, or peripheral vascular resistance; decreased function of the skeletal muscle pumps; and decreased blood volume. Because cerebral blood flow primarily depends on systolic pressure, people with impaired cerebral circulation may experience symptoms of weakness, ataxia, dizziness, and syncope when their arterial pressure falls even slightly. This may happen in older adults who are immobilized for even brief periods or whose blood volume is decreased owing to inadequate fluid intake or overzealous use of diuretics. It is seen more often in institutionalized older adults (up to 68%) compared to those living in the community (6%).53

### Reduced Blood Volume

Orthostatic hypotension often is an early sign of reduced blood volume or fluid deficit. When blood volume is decreased, the vascular compartment is only partially filled. Although cardiac output may be adequate when a person is in the recumbent position, it often decreases to the point of causing weakness and fainting when the person assumes the standing position. Common causes of orthostatic hypotension related to hypovolemia are excessive use of diuretics, excessive diaphoresis, loss of gastrointestinal fluids through vomiting and diarrhea, and loss of fluid volume associated with prolonged bed rest.

### Bed Rest and Impaired Mobility

Prolonged bed rest promotes a reduction in plasma volume, a decrease in venous tone, failure of peripheral vasoconstriction, and weakness of the skeletal muscles that support the veins and assist in returning blood to the heart. Physical deconditioning follows even short periods of bed rest. After 3 to 4 days, the blood volume is decreased. Loss of vascular and skeletal muscle tone is less predictable but probably becomes maximal after approximately 2 weeks of bed rest. Orthostatic intolerance is a recognized problem of space flight—a potential risk after reentry into the earth’s gravitational field.

### Drug-Induced Hypotension

Antihypertensive drugs and psychotropic drugs are the most common cause of chronic orthostatic hypotension. In most cases, the orthostatic hypotension is well tolerated. However, if the hypotension causes light-headedness or syncope, the dosage of the drug is usually reduced or a different drug substituted.

### Disorders of the Autonomic Nervous System

The SNS plays an essential role in adjustment to the upright position. Sympathetic stimulation increases heart rate and cardiac contractility and causes constriction of peripheral veins and arterioles. Orthostatic hypotension caused by altered ANS function is common in peripheral neuropathies associated with diabetes mellitus, after injury or disease of the spinal cord, or as the result of a cerebral vascular accident in which sympathetic outflow from the brain stem is disrupted. The American Autonomic Society and the American Academy of Neurology have distinguished three forms of primary ANS dysfunction: (1) pure autonomic failure, which is defined as a sporadic, idiopathic cause of persistent orthostatic hypotension and other manifestations of autonomic failure such as urinary retention, impotence, or decreased sweating; (2) Parkinson disease with autonomic failure; and (3) multiple-system atrophy (Shy-Drager syndrome).52 The Shy-Drager syndrome usually develops in middle to late life as orthostatic hypotension associated with uncoordinated movements, urinary incontinence, constipation, and other signs of neurologic deficits referable to the corticospinal, extrapyramidal, corticobulbar, and cerebellar systems.
ORTHOSTATIC HYPOTENSION

- Orthostatic or postural hypotension represents an abnormal drop in blood pressure on assumption of the upright position due to pooling of blood in the lower part of the body.
- Orthostatic hypotension may be accompanied by a decrease in cerebral perfusion that causes a feeling of light-headedness, dizziness, and, in some cases, fainting. It poses a particular threat for falls in the elderly.

Diagnosis

Orthostatic hypotension can be assessed with the auscultatory method of blood pressure measurement. Measurements should be made when the person is supine, after standing for 1 minute, and again after standing for 3 minutes. Because it takes approximately 5 to 10 minutes for the blood pressure to stabilize after lying down, it is recommended that the patient be supine for this period before standing. It is strongly recommended that a second person be available when blood pressure is measured in the standing position to prevent injury should the person become faint. The seated position may be used in persons who are unable to stand; however, the postural blood pressure changes may be missed.

The detection of orthostatic hypotension may require numerous blood pressure measurements under different conditions. The time of day is important because postural hypotension is often worse in the morning when the person rises from bed. Food and alcohol can also exacerbate orthostatic hypotension, as can activities that raise intrathoracic pressure (urination, defecation, coughing). An orthostatic hypotensive response may be immediate or delayed. Prolonged standing or a tilt table test may be needed to detect a delayed response. With a tilt table, the recumbent person can be moved to a head-up position without voluntary movement when the table is tilted. The tilt table also has the advantage of rapidly and safely returning persons with a profound postural drop in blood pressure to the horizontal position.

The heart rate response to postural change may provide valuable information about the cause of orthostatic hypotension. A minimal increase in heart rate (<10 beats/minute) in the face of hypotension suggests impairment of baroreflex function, whereas tachycardia (>100 beats/minute) is suggestive of volume depletion or orthostatic intolerance. Because of the age-related decrease in baroreflex function, the absence of an increase in heart rate does not rule out volume depletion in the older adult.

People with a position-related drop in blood pressure sufficient to qualify as orthostatic hypotension should be evaluated to determine the cause and seriousness of the condition. A history should be taken to elicit information about symptoms, particularly dizziness and history of syncope and falls; medical conditions, particularly those such as diabetes mellitus that predispose to orthostatic hypotension; use of prescription and over-the-counter drugs; and symptoms of ANS dysfunction, such as erectile or bladder dysfunction. A physical examination should document blood pressure in both arms and the heart rate while in the supine, sitting, and standing positions and should note the occurrence of symptoms. Noninvasive, 24-hour ambulatory blood pressure monitoring may be used to determine blood pressure responses to other stimuli of daily life, such as food ingestion and exertion.

Treatment

Treatment of orthostatic hypotension usually is directed toward alleviating the cause or, if this is not possible, toward helping people learn ways to cope with the disorder and prevent falls and injuries. Medications that predispose to postural hypotension should be avoided. Correcting the fluid deficit and trying a different antihypertensive medication are examples of measures designed to correct the cause. Measures designed to help persons prevent symptomatic orthostatic drops in blood pressure include gradual ambulation to allow the circulatory system to adjust (i.e., sitting on the edge of the bed for several minutes and moving the legs to initiate skeletal muscle pump function before standing); avoidance of situations that encourage excessive vasodilation (e.g., drinking alcohol, exercising vigorously in a warm environment); and avoidance of excess diuresis (e.g., use of diuretics), diaphoresis, or loss of body fluids. Tight-fitting elastic support hose or an abdominal support garment may help prevent pooling of blood in the lower extremities and abdomen.

Pharmacologic treatment may be used when nonpharmacologic methods are unsuccessful. A number of types of drugs can be used for this purpose. Mineralocorticoids (e.g., fludrocortisone) can be used to reduce salt and water loss and probably increase \( \alpha \)-adrenergic sensitivity. Vasopressin-2 receptor agonists (desmopressin as a nasal spray) may be used to reduce nocturnal polyuria. Sympathomimetic drugs that act directly on the resistance vessels (e.g., phentolamine, noradrenaline, clonidine) or on the capacitance vessels (e.g., dihydroergotamine) may be used. Many of these agents have undesirable side effects. Octreotide, a somatostatin analog that inhibits the release of vasodilatory gastrointestinal peptides, may prove useful in persons with postprandial hypotension.

Orthostatic hypotension refers to an abnormal decrease in systolic and diastolic blood pressures that occurs on assumption of the upright position. An important consideration in orthostatic hypotension is the occurrence of dizziness and syncope. Among the factors that contribute to its occurrence are decreased fluid volume, medications, aging, defective function of the ANS, and the effects of immobility. Diagnosis of orthostatic hypotension relies on blood pressure measurements in the supine and upright positions,
and a history of symptomatology, medication use, and disease conditions that contribute to a postural drop in blood pressure. Treatment includes correcting the reversible causes and assisting the person to compensate for the disorder and prevent falls and injuries.

**REVIEW EXERCISES**

1. A 47-year-old African American man who is an executive in a law firm has his blood pressure taken at a screening program and is told that his pressure is 142/90 mm Hg. His father and older brother have hypertension, and his paternal grandparents had a history of stroke and myocardial infarction. The patient enjoys salty foods and routinely uses a saltshaker to add salt to meals his wife prepares, drinks about four beers while watching television in the evening, and gained 15 lb in the past year. Although his family has encouraged him to engage in physical activities with them, he states he is either too busy or too tired.

   **A.** According to the JNC 7 guidelines, into what category does the patient’s blood pressure fall?
   **B.** What are his risk factors for hypertension?
   **C.** Explain how an increased salt intake might contribute to his increase in blood pressure.
   **D.** What lifestyle changes would you suggest to the patient? Explain the rationale for your suggestions.

2. A 36-year-old woman enters the clinic complaining of headache and not feeling well. Her blood pressure is 175/90 mm Hg. Her renal test results are abnormal, and follow-up tests confirm that she has a stricture of the left renal artery.

   **A.** Would this woman’s hypertension be classified as primary or secondary?
   **B.** Explain the physiologic mechanisms underlying her blood pressure elevation.

3. A 75-year-old woman residing in an extended care facility has multiple health problems, including diabetes, hypertension, and heart failure. Lately, she has been feeling dizzy when she stands up, and she has almost fallen on several occasions. Her family is concerned and wants to know why this is happening and what they can do to prevent her from falling and breaking her hip.

   **A.** How would you go about assessing this woman for orthostatic hypotension?
   **B.** What are the causes of orthostatic hypotension in elderly persons?
   **C.** How might this woman’s medical conditions and their treatment contribute to her orthostatic hypotension?

Cardiovascular disease (CVD) is the leading cause of death in men and women in the United States. Because of economic advances, social structures, and demographics, low- and middle-income countries are seeing an accelerated increase in CVD, surpassing infectious diseases. It is estimated that the direct and indirect costs of CVD in the United States alone were $316.4 billion for 2010. To reduce this increase in morbidity, mortality, and cost, strategies such as population-based public health measures, preventive programs for high-risk subgroups, and the allocation of resources for treatments for CVD can be useful.

In an attempt to focus on common heart problems that affect persons in all age groups, this chapter is organized into six sections: disorders of the pericardium, coronary artery disease (CAD), cardiomyopathies, infectious and immunologic disorders of the heart, valvular heart disease, and heart disease in infants and children.

The pericardium, sometimes referred to as the pericardial sac, is a double-layered serous membrane that isolates the heart from other thoracic structures, maintains its position in the thorax, prevents it from overfilling, and serves as a barrier to infection. The pericardium consists of two layers: a thin inner layer, called the visceral pericardium, that adheres to the epicardium; and an outer fibrous layer, called the parietal pericardium, that is attached to the great vessels that enter and leave the heart, the sternum, and the diaphragm. These two layers of the pericardium are separated by a potential space, the pericardial cavity, which contains about 50 mL of serous fluid. This fluid acts as a lubricant that prevents frictional forces from developing as the heart contracts and relaxes. Although there is little blood supply to the pericardium, it is well innervated and inflammation can cause severe pain.

The pericardium is subject to many of the same pathologic processes (e.g., congenital disorders, infections, trauma, immune mechanisms, and neoplastic disease) that affect other structures of the body. Pericardial disorders frequently are associated with or result from another disease in the heart or the surrounding structures (Chart 32.1).

**Chart 32.1 Classification of Disorders of the Pericardium**

### Inflammation
- Acute inflammatory pericarditis
- 1. Infectious
  - Viral (echovirus, coxsackievirus, and others)
  - Bacterial (e.g., tuberculosis, *Staphylococcus*, *Streptococcus*)
  - Fungal
- 2. Immune and collagen disorders
  - Rheumatic fever
  - Rheumatoid arthritis
  - Systemic lupus erythematosus
- 3. Metabolic disorders
  - Uremia and dialysis
  - Myxedema
- 4. Ischemia and tissue injury
  - Myocardial infarction
  - Cardiac surgery
  - Chest trauma
- 5. Physical and chemical agents
  - Radiation therapy
  - Untoward reactions to drugs, such as hydralazine, procainamide, and anticoagulants
  - Chronic inflammatory pericarditis
  - Can be associated with most of the agents causing an acute inflammatory response

### Neoplastic Disease
- 1. Primary
- 2. Secondary (e.g., carcinoma of the lung or breast, lymphoma)

### Congenital Disorders
- 1. Complete or partial absence of the pericardium
- 2. Congenital pericardial cysts

**Key Points**

- The pericardium isolates the heart from other thoracic structures, maintains its position in the thorax, and prevents it from overfilling.
- The two layers of the pericardium are separated by a thin layer of serous fluid, which prevents frictional forces from developing between the visceral and parietal layers of the pericardium.
- Disorders that produce inflammation of the pericardium interfere with the friction-reducing properties of the pericardial fluid and produce pain.
- Disorders that increase the fluid volume of the pericardial sac interfere with cardiac filling and produce a subsequent reduction in cardiac output.
Acute Pericarditis

Pericarditis represents an inflammatory process of the pericardium. Acute pericarditis, defined as signs and symptoms resulting from a pericardial inflammation of less than 2 weeks, may occur as an isolated disease or as the result of systemic disease. Viral infections (especially infections with coxsackieviruses and echoviruses) are the most common cause of pericarditis and probably are responsible for many cases classified as idiopathic. Other causes of acute pericarditis include bacterial or mycobacterial infections, connective tissue diseases (e.g., systemic lupus erythematosus, rheumatoid arthritis), uremia, postcardiac surgery, neoplastic invasion of the pericardium, radiation, trauma, drug toxicity, and contiguous inflammatory processes of the myocardium or lung.3,4

Like other inflammatory conditions, acute pericarditis often is associated with increased capillary permeability. The capillaries that supply the serous pericardium become permeable, allowing plasma proteins, including fibrinogen, to leave the capillaries and enter the pericardial space. This results in an exudate that varies in type and amount according to the causative agent. Acute pericarditis frequently is associated with a fibrinous (fibrin-containing) exudate (Fig. 32.1), which heals by resolution or progresses to deposition of scar tissue and formation of adhesions between the layers of the serous pericardium. Inflammation also may involve the superficial myocardium and the adjacent pleura.

Clinical Manifestations

The manifestations of acute pericarditis include a triad of chest pain, pericardial friction rub, and electrocardiographic (ECG) changes. The clinical findings may vary according to the causative agent. Nearly all people with acute pericarditis have chest pain. The pain usually is abrupt in onset and sharp, occurring in the precordial area, and may radiate to the neck, back, abdomen, or side. Pain in the scapular ridge may be due to irritation of the phrenic nerve. The pain typically is worse with deep breathing, coughing, swallowing, and positional changes because of changes in venous return and cardiac filling. The person often finds relief by sitting up and leaning forward. It is important to differentiate the chest pain from pericarditis from acute myocardial infarction or pulmonary embolism.

Diagnosis

Diagnosis of acute pericarditis is based on clinical manifestations, ECG, chest radiography, and echocardiography. A pericardial friction rub, often described as high pitched or scratchy, results from the rubbing and friction between the inflamed pericardial surfaces. The friction rub is typically described as having three components, which correspond to atrial systole, ventricular systole, and rapid filling of the ventricle. Because it results from the rubbing together of the inflamed pericardial surfaces, large effusions are unlikely to produce a friction rub. Except in uremic pericarditis, the ECG changes in pericarditis typically evolve through four progressive stages: diffuse ST-segment elevations and PR-segment depression, normalization of the ST and PR segments, widespread T-wave inversions, and normalization of T waves. Laboratory markers of systemic inflammation may also be present, including an elevated white blood cell count, elevated erythrocyte sedimentation rate (ESR), and increased C-reactive protein (CRP). Increased CRP is not present in all cases. However, it can be used to monitor disease activity and length of treatment needed.

Treatment

Acute idiopathic pericarditis is frequently self-limiting and presumed to be viral. Symptoms are usually successfully treated with nonsteroidal anti-inflammatory drugs (NSAIDs).3,4 Colchicine can be added to the treatment regimen and has also been shown to be of benefit in people who have a slow response to NSAIDs. Colchicine produces its anti-inflammatory effects by preventing the polymerization of microtubules, which leads to the inhibition of leukocyte migration and phagocytosis. When infection is present, antibiotics specific for the causative agent usually are prescribed. Corticosteroids may be used for treatment of persons with connective tissue disease or severely symptomatic pericarditis that is not responsive to NSAIDs and colchicine. Corticosteroids should be avoided if possible due to an increased number of recurrences associated with use, if not related to autoimmune diseases. However, if it cannot be avoided, only a short course of corticosteroids should be initiated.
Relapsing pericarditis can occur in up to 30% of people with acute pericarditis who respond satisfactorily to treatment. A minority of these people develop recurrent bouts of pericardial pain, which can sometimes be chronic and debilitating. The process commonly is associated with autoimmune disorders, such as lupus erythematosus, rheumatoid arthritis, scleroderma, and myxedema, but may also occur following viral pericarditis. Treatment includes the use of anti-inflammatory medications such as NSAIDs initially and then treatment with colchicines. If reoccurrence continues, colchicine prophylaxis is warranted. If colchicines are not tolerated, then low-dose corticosteroids can be initiated.

**Pericardial Effusion and Cardiac Tamponade**

*Pericardial effusion* refers to the accumulation of fluid in the pericardial cavity, usually as a result of an inflammatory or infectious process. It may also develop as the result of neoplasms, cardiac surgery, trauma, cardiac rupture due to myocardial infarction, and dissecting aortic aneurysm. The pericardial cavity has little reserve volume. The pressure–volume relationship between the normal pericardial and cardiac volumes can be dramatically affected by only small amounts of fluid once critical levels of effusion are present. Because right heart filling pressures are lower than that of the left heart, increases in pressure are usually reflected in signs and symptoms of right-sided heart failure before equalization is achieved.

**Pathogenesis**

The amount of fluid, the rapidity with which it accumulates, and the elasticity of the pericardium determine the effect the effusion has on cardiac function. Small pericardial effusions may produce no symptoms or abnormal clinical findings. Even a large effusion that develops slowly may cause few or no symptoms, provided the pericardium is able to stretch and avoid compressing the heart. However, a sudden accumulation of even 200 mL may raise intracardiac pressure to levels that seriously limit the venous return to the heart. Symptoms of cardiac compression also may occur with relatively small accumulations of fluid if the pericardium has become thickened by scar tissue or neoplastic infiltrations.

Pericardial effusion can lead to a condition called *cardiac tamponade*, in which there is compression of the heart due to the accumulation of fluid, pus, or blood in the pericardial sac. This life-threatening condition can be caused by infections, neoplasms, and bleeding. Cardiac tamponade results in increased intracardiac pressure, progressive limitation of ventricular diastolic filling, and reductions in stroke volume and cardiac output. The severity of the condition depends on the amount of fluid present and the rate at which it accumulates.

A significant accumulation of fluid in the pericardium results in increased adrenergic stimulation, which leads to tachycardia and increased cardiac contractility. There is elevation of central venous pressure, jugular vein distention, a fall in systolic blood pressure, narrowed pulse pressure, and signs of circulatory shock. The heart sounds may become muffled because of the insulating effects of the pericardial fluid and reduced cardiac function. People with slowly developing cardiac tamponade usually appear acutely ill, but not to the extreme seen in those with rapidly developing tamponade.

**Diagnosis**

A key diagnostic finding is *pulsus paradoxus*, or an exaggeration of the normal variation in the systemic arterial pulse volume with respiration. Normally, the decrease in intrathoracic pressure that occurs during inspiration accelerates venous flow, increasing right atrial and right ventricular filling. This causes the interventricular septum to bulge to the left, producing a slight decrease in left ventricular filling, stroke volume output, and systolic blood pressure. In cardiac tamponade, the left ventricle (LV) is compressed from within by movement of the interventricular septum and from without by fluid in the pericardium (Fig. 32.2). This produces a marked decrease in central venous pressure, jugular vein distention, and systolic blood pressure.

**FIGURE 32.2** Effects of respiration and cardiac tamponade on ventricular filling and cardiac output. During inspiration, venous flow into the right heart increases, causing the interventricular septum to bulge into the LV. This produces a decrease in left ventricular volume, with a subsequent decrease in stroke volume output. In cardiac tamponade, the fluid in the pericardial sac produces further compression of the LV, causing an exaggeration of the normal inspiratory decrease in stroke volume and systolic blood pressure.
in left ventricular filling and left ventricular stroke volume output, often within a beat of the beginning of inspiration. Pulsus paradoxus can be determined by palpation, cuff sphygmomanometry, or arterial pressure monitoring. With pulsus paradoxus, the arterial pulse as palpated at the carotid or femoral artery becomes weakened or absent during inspiration and becomes stronger during expiration. Palpation provides only a gross estimate of the degree of pulsus paradoxus. It is more sensitively estimated when the blood pressure cuff is used to compare the Korotkoff sounds during inspiration and expiration—a decline in systolic pressure greater than 10 mm Hg during inspiration is suggestive of tamponade. Arterial pressure monitoring allows visualization of the arterial pressure waveform and measurement of the blood pressure drop during inspiration.

The echocardiogram is a rapid, accurate, and widely used method of evaluating pericardial effusion. The ECG often reveals nonspecific T-wave changes and low QRS voltage. Usually only moderate to large effusions can be detected by chest radiography.

**Treatment**

Treatment of pericardial effusions depends on the progression to cardiac tamponade. In small pericardial effusions or mild cardiac tamponade, NSAIDs, colchicine, or corticosteroids may minimize fluid accumulation. Pericardiocentesis, or removal of fluid from the pericardial sac, often with the aid of echocardiography, is the initial treatment of choice. Closed pericardiocentesis, which is performed with a needle inserted through the chest wall, may be an emergency lifesaving measure in severe cardiac tamponade. Open pericardiocentesis may be used for recurrent or loculated effusions (i.e., those confined to one or more pockets in the pleural space), during which biopsies can be obtained and pericardial windows created. Aspiration and laboratory evaluation of the pericardial fluid may be used to identify the causative agent.

**Constrictive Pericarditis**

In constrictive pericarditis, fibrous, calcified scar tissue develops between the visceral and parietal layers of the serous pericardium. In time, the scar tissue contracts and interferes with diastolic filling of the heart, at which point cardiac output and cardiac reserve become fixed. The equalization of end-diastolic pressures in all four cardiac chambers is the pathophysiologic hallmark of constrictive pericarditis. Effusive–constrictive pericarditis, a combination of effusion–tamponade and constriction, is a syndrome that develops in a significant number of people with pericardial disease. Because it occurs most often during a subacute or chronic course of pericardial disease, it is most likely due to a transition from acute pericarditis with pericardial effusion to constrictive pericarditis. It usually is detected when hemodynamic measurements fail to stabilize after pericardiocentesis. There are many causes, but the most common is idiopathic with the exception of possibly caused from malignant disease, radiation, and tuberculosis. People with the disorder usually require pericardiectomy.

**Etiology and Clinical Manifestations**

Long-standing inflammation from mediastinal radiation, cardiac surgery, or infection is usually the cause of constrictive pericarditis. Ascites is a prominent early finding and may be accompanied by pedal edema, dyspnea on exertion, and fatigue. The jugular veins also are distended. The Kussmaul sign is an inspiratory distention of the jugular veins caused by the inability of the right atrium, encased in its rigid pericardium, to accommodate the increase in venous return that occurs with inspiration. Exercise intolerance, muscle wasting, and weight loss develop in end-stage constrictive pericarditis.

**Diagnosis**

Chest radiography and Doppler and transesophageal echocardiography are helpful in the diagnosis of constrictive pericarditis. Doppler echocardiogram and cardiac catheterization are especially useful in the differentiation of constrictive pericarditis from restrictive cardiomyopathy, as are computed tomography (CT) and magnetic resonance imaging (MRI). In chronic constrictive pericarditis, surgical removal or resection of the pericardium (i.e., pericardiectomy) is often the treatment of choice.

**IN SUMMARY**

The pericardium is a two-layered membranous sac that isolates the heart from other thoracic structures, maintains its position in the thorax, and prevents it from overfilling; it also may help prevent infection. Disorders of the pericardium include acute and chronic pericarditis, pericardial effusion and cardiac tamponade, and constrictive and effusive–constrictive pericarditis. The major threat of pericardial disease is compression of the heart chambers.

Acute pericarditis may be infectious in origin, or it may be due to systemic diseases. It is characterized by chest pain, ECG changes, and pericardial friction rub. Recurrent pericarditis is usually associated with autoimmune disorders, and symptoms may be minimal. Pericardial effusion, either acute or chronic, refers to the presence of an exudate in the pericardial cavity. It can increase intracardiac pressure, compress the heart, and interfere with venous return to the heart. The amount of exudate, the rapidity with which it accumulates, and the elasticity of the pericardium determine the effect the effusion has on cardiac function. Cardiac tamponade represents a life-threatening compression of the heart resulting from excess fluid in the pericardial sac. In constrictive pericarditis, scar tissue develops between the visceral and parietal layers of the serous pericardium. In time, the scar tissue contracts and interferes with cardiac filling.
abdominal obesity, and physical inactivity. Individuals with diabetes and the metabolic syndrome are at particularly increased risk for development of CVD and have significant morbidity from the disease.

Coronary Circulation

The two main coronary arteries, the left and the right, arise from the coronary sinus just above the aortic valve (Fig. 32.3). The left coronary artery supplies blood flow to the anterior and left lateral portions of the LV. The left main coronary artery then divides into the left anterior descending and circumflex branches. The left anterior descending artery passes down through the groove between the two ventricles, giving off diagonal branches, which supply the LV, and perforating branches, which supply the anterior portion of the interventricular septum and the anterior papillary muscle of the LV. The circumflex branch of the left coronary artery passes to the left and moves posteriorly in the groove that separates the left atrium and ventricle, giving off branches that supply the left lateral wall of the LV. The right coronary artery lies in the right atrioventricular groove, and its branches supply most of the right ventricle and the posterior part of the LV in 80% to 90% of people. The right coronary artery usually moves to the back of the heart, where it forms the posterior descending artery, which normally supplies the posterior portion of the heart, interventricular septum, sinoatrial (SA) and atrioventricular (AV) nodes, and posterior papillary muscle. By convention, the coronary artery that supplies the posterior third of the septum (either the right coronary artery or the left circumflex) is called dominant. In a right dominant circulation, present in approximately four fifths of people, the left circumflex perfuses the lateral wall of the LV.

The term coronary artery disease (CAD) describes heart disease caused by impaired coronary blood flow. In most cases, CAD is caused by atherosclerosis, which affects not only the coronary arteries but arteries in other areas of the body. Diseases of the coronary arteries can cause myocardial ischemia and angina, myocardial infarction or heart attack, cardiac arrhythmias, conduction defects, heart failure, and sudden death. Each year, more than 1.6 million Americans have new or recurrent myocardial infarctions; one third of those die within the first 24 hours, and many of those who survive suffer significant morbidity. Major risk factors for CAD include cigarette smoking, elevated blood pressure, elevated serum total and low-density lipoprotein (LDL) cholesterol, low serum high-density lipoprotein (HDL) cholesterol, diabetes, advancing age, abdominal obesity, and physical inactivity. Individuals with diabetes and the metabolic syndrome are at particularly increased risk for development of CVD and have significant morbidity from the disease.

After completing this section of the chapter, you should be able to meet the following objectives:

- Describe blood flow in the coronary circulation and relate it to the determinants of myocardial oxygen supply and demand.
- Define the term acute coronary syndrome and distinguish among chronic stable angina, unstable angina, non–ST-segment elevation myocardial infarction, and ST-segment elevation myocardial infarction in terms of pathology, symptomatology, ECG changes, and serum cardiac markers.
- Define the treatment goal for acute coronary syndrome.

The term coronary artery disease (CAD) describes heart disease caused by impaired coronary blood flow. In most cases, CAD is caused by atherosclerosis, which affects not only the coronary arteries but arteries in other areas of the body. Diseases of the coronary arteries can cause myocardial ischemia and angina, myocardial infarction or heart attack, cardiac arrhythmias, conduction defects, heart failure, and sudden death. Each year, more than 1.6 million Americans have new or recurrent myocardial infarctions; one third of those die within the first 24 hours, and many of those who survive suffer significant morbidity.

Major risk factors for CAD include cigarette smoking, elevated blood pressure, elevated serum total and low-density lipoprotein (LDL) cholesterol, low serum high-density lipoprotein (HDL) cholesterol, diabetes, advancing age, abdominal obesity, and physical inactivity. Individuals with diabetes and the metabolic syndrome are at particularly increased risk for development of CVD and have significant morbidity from the disease.
LV, and the right coronary artery supplies the entire right ventricular free wall and the posterior third of the septum. Thus, occlusion of the right as well as the left coronary artery can cause left ventricular damage.

The large epicardial coronary arteries lie on the surface of the heart, with smaller intramyocardial arteries branching and penetrating the myocardium before merging with a network or plexus of subendocardial vessels. Although there are no connections between the large coronary arteries, there are anastomotic channels that join the small arteries. With gradual occlusion of the larger vessels, the smaller collateral vessels increase in size and provide alternative channels for blood flow. One of the reasons CAD does not produce symptoms until it is far advanced is that the collateral channels develop at the same time the atherosclerotic changes are occurring.

Blood flow in the coronary arteries is controlled largely by physical, neural, and metabolic factors. The openings for the coronary arteries originate in the root of the aorta just outside the aortic valve. Thus, the main factor responsible for perfusion of the coronary arteries is the aortic blood pressure, which is generated by the heart itself. Myocardial blood flow, in turn, is largely regulated by the metabolic activity of the myocardium and autoregulatory mechanisms that control vessel dilation. In addition to generating the aortic pressure that moves blood through the coronary vessels, the contracting heart muscle influences its own blood supply by compressing the intramyocardial and subendocardial blood vessels during systole. The autonomic nervous system exerts its effects on coronary blood flow through changes in heart rate, cardiac contractility, and blood pressure.

Coronary blood flow is largely regulated by the need of the cardiac muscle for oxygen. Even under normal resting conditions, the heart extracts and uses 70% of oxygen in blood flowing through the coronary arteries. Because there is little oxygen reserve in the blood, the coronary arteries must increase their flow to meet the metabolic needs of the myocardium during periods of increased activity. The normal resting blood flow through the coronary arteries averages approximately 225 mL/min or about 4% to 5% of the total cardiac output. During strenuous exercise, coronary flow may increase four- to fivefold to meet the energy requirements of the heart.

One of the major determinants of coronary blood flow is the metabolic activity of the heart. Numerous agents, referred to as metabolites, are thought to act as mediators for the vasodilation that accompanies increased cardiac work. These substances, which include potassium ions, lactic acid, carbon dioxide, and adenosine, are released from working myocardial cells. Of these substances, adenosine appears to have the greatest vasodilator effect and is perhaps the critical mediator of local blood flow.

The endothelial cells that line blood vessels, including the coronaries, normally form a barrier between the blood and the arterial wall. They also synthesize several substances that, when released, can affect relaxation or constriction of the smooth muscle in the arterial wall. Potent vasodilators produced by the endothelium include nitric oxide, prostacyclin, and endothelium-derived hyperpolarizing factor (EDHF). The most important of these is nitric oxide. Most vasodilators and vasodilating stimuli exert their effects through nitric oxide. Products from aggregating platelets, thrombin, the products of mast cells, and increased shear force, which is responsible for so-called flow-mediated vasodilation, stimulate the synthesis and release of nitric oxide. The endothelium also is the source of vasoconstricting factors, the best known of which are the endothelins.

**Myocardial Oxygen Supply and Demand**

The coronary circulation supplies the heart muscle with the oxygen and nutrients it needs to pump blood out to the rest of the body. In a person who is resting, 75% of the oxygen in the blood that passes through the myocardium is extracted. As the metabolic needs of the body change, cardiac function and coronary blood flow must adapt to meet these needs. If there is an imbalance in the myocardial oxygen supply and demand, myocardial ischemia and angina, myocardial infarction, or even sudden death can occur.

**Myocardial Oxygen Supply.** Myocardial oxygen supply is determined by the coronary arteries and capillary inflow and the ability of hemoglobin to transport and deliver oxygen to the heart muscle. Important factors in the transport and delivery of oxygen include the fraction of inspired oxygen in the blood and the number of red blood cells with normally functioning hemoglobin. Even with adequate coronary blood flow, myocardial ischemia can occur in situations of hypoxia, anemia, or carbon monoxide poisoning.

**Myocardial Oxygen Demand.** There are three major determinants of myocardial oxygen demand (MVO2): the heart rate, left ventricular contractility, and systolic pressure or myocardial wall stress or tension (Fig. 32.4). The heart rate is the most important factor in myocardial oxygen demand, for two reasons:

Chapter 32  Disorders of Cardiac Function  799

Understanding  Myocardial Blood Flow

Blood flow in the coronary vessels that supply the myocardium is influenced by (1) the aortic pressure, (2) autoregulatory mechanisms, and (3) compression of the intramyocardial vessels by the contracting heart muscle.

Aortic Pressure

The two main coronary arteries that supply blood flow to the myocardium arise in the sinuses behind the two cusps of the aortic valve. Because of their location, the pressure and flow of blood in the coronary arteries reflects that of the aorta. During systole, when the aortic valve is open, the velocity of blood flow and position of the valve cusps cause the blood to move rapidly past the coronary artery inlets, and during diastole, when the aortic valve is closed, blood flow and the aortic pressure are transmitted directly into the coronary arteries.

Autoregulatory Mechanisms

The heart normally extracts 60% to 80% of the oxygen in the blood delivered to it, leaving little in reserve. Accordingly, oxygen delivery during periods of increased metabolic demand depends on autoregulatory mechanisms that regulate blood flow through a change in vessel tone and diameter. During increased metabolic demand, vasodilation produces an increase in blood flow; during decreased demand, vasoconstriction or return of vessel tone to normal produces a reduction in flow. The mechanisms that link the metabolic activity of the heart to changes in vessel tone result from vasoactive mediators released from myocardial cells and the vascular endothelium.
The large coronary arteries lie on the epicardial surface of the heart, with smaller intramyocardial vessels branching off and moving through the myocardium before merging with a plexus of vessels that supply the subendocardial muscle with blood. During systole, the contracting cardiac muscle has a squeezing effect on the intramyocardial vessels, while at the same time producing an increase in intraventricular pressure that pushes against and compresses the subendocardial vessels. As a result, blood flow to the subendocardial muscle is greatest during diastole. Because the time spent in diastole becomes shortened as the heart rate increases, myocardial blood flow can be greatly reduced during sustained periods of tachycardia.

1. As the heart rate increases, myocardial oxygen consumption or demand also increases.
2. Subendocardial coronary blood flow is reduced because of the decreased diastolic filling time with increased heart rates.7,8

Myocardial contractility is the intrinsic ability of the heart muscle to shorten and generate force. It reflects the interaction between calcium ions and the contractile proteins (actin and myosin) of the muscle fibers.8 It is normally determined by the rate of pressure development and muscle shortening. With increased myocardial contractility, the rate of change in wall stress is increased, which in turn increases myocardial oxygen uptake. Factors that increase contractility, such as exercise, sympathetic nervous system stimulation, and inotropic agents, all increase MVO2.6

Wall stress develops when tension is applied to a given area. Left ventricular wall stress can be thought of as the average tension that individual muscle fibers must generate to shorten against a developed intraventricular pressure. It is proportional to the product of the intraventricular pressure and ventricle radius, divided by the thickness of the ventricle wall. Thus, at a given pressure, wall stress is increased by an increase in radius (ventricular dilation), and it is increased by a decrease in wall thickness. The term preload is used to describe the distending force of the ventricular wall as it fills prior to contraction.9 Changes in preload are assessed by using the left ventricular end-diastolic pressure. This can be measured indirectly by using the pulmonary artery occlusive (or wedge) pressure, obtained through a pulmonary artery catheter. Afterload is the “load” against which the heart must contract to eject blood. A major component of the left ventricular afterload is the aortic pressure, or pressure that the ventricle must generate to eject blood into the aorta.9 An increase in wall stress, whether caused by an increase in preload or afterload, increases MVO2 because as cardiac muscle fibers develop more tension, they require a greater rate of adenosine triphosphate (ATP) use. Because wall stress is inversely related to wall thickness, ventricular hypertrophy serves as an adaptive mechanism by which the ventricle is able to offset the increase in wall stress that accompanies increased aortic pressure or aortic valve stenosis.
Assessment of Coronary Blood Flow and Myocardial Perfusion

Among the methods used in the evaluation of coronary blood flow and myocardial perfusion are electrocardiography, exercise stress testing, echocardiography, and Doppler ultrasonographic imaging; cardiac MRI and CT; and cardiac catheterization and angiography. These assessment modalities vary widely and are undergoing constant technological advances.

Electrocardiography. The 12-lead ECG is the most frequently used cardiovascular diagnostic procedure. It can be used not only for the diagnosis and treatment of CAD but also for the identification of ventricular conduction defects, arrhythmias, electrolyte imbalances, drug effects, and genetically mediated electrical or structural abnormalities. The standard 12-lead ECG uses electrodes to record electrical potential differences, generated by ion currents (action potentials) during the cardiac cycle, between prescribed sites on the body. Proper electrode placement and patient position are important because they can change the recorded amplitudes and axes of the ECG, which can affect interpretation.

Ambulatory ECG monitoring often is done to detect transient ST-segment and T-wave changes that occur and are not accompanied by symptoms (i.e., silent ischemia). Continuous ambulatory ECG monitoring can be done using a Holter monitor and/or event monitor. Another method, called signal-averaged or high-resolution ECG, accentuates the QRS complex so that low-amplitude afterpotentials can be identified. These low-amplitude afterpotentials can sometimes be correlated with high risk of ventricular arrhythmias, and sudden death may be detected.

Exercise Stress Testing. Exercise stress testing is a means of observing cardiac function under stress and is typically performed in adults with symptoms of known or suspected ischemic heart disease. It is also used to check for physiologic response post MI or revascularization, functional capacity for an exercise program and/or cardiac rehabilitation, efficacy of medication or surgical treatments; the severity of arrhythmias; preoperatively to assess functional status; and to evaluate intermittent claudication.10

Treadmill exercise, which is the most commonly used method of cardiovascular stress testing, requires higher levels of myocardial performance than other forms of exercise. The goal is to achieve maximum level of exertion for their age if possible. While trying to do this, blood pressure is monitored during exercise testing, and the ECG pattern is recorded for the purposes of determining heart rate and detecting myocardial ischemic changes. Chest pain, severe shortness of breath, arrhythmias, ST-segment changes on the ECG, or a decrease in blood pressure suggests CAD. If one or more of these signs or symptoms are present, the test is usually terminated.

Pharmacologic stress testing may be used to simulate the stress of exercise in persons who cannot participate in active forms of exercise because of orthopedic, neurologic, peripheral vascular disorders, or other conditions. The intravenous infusion of dipyridamole, adenosine, or dobutamine can be used. Dipyridamole blocks the cellular reabsorption of adenosine, an endogenous vasodilator, and increases coronary blood flow three to five times above baseline levels. In people with significant CAD, the resistance vessels distal to the stenosis already are maximally dilated to maintain normal resting flow. In these persons, further vasodilation does not produce an increase in blood flow. Intravenous injection of adenosine has comparable effects. Dobutamine, a sympathomimetic agent, increases myocardial contractility and stroke volume. During stress echocardiography, low-dose dobutamine identifies myocardial viability and high-dose dobutamine identifies myocardial ischemia.10

Exercise stress testing in certain populations can pose a challenge. Women who engage in an exercise stress test are less sensitive to exercise-induced ST-segment depression. To increase accuracy of test results in women, radionuclide testing has been suggested but is not in the American College of Cardiology/American Heart Association (ACC/AHA) guidelines. Testing in older adults is also challenging due to their decrease in exercise capacity. They usually have light-headedness and fatigue due to deconditioning and muscle fatigue. This may require a modified protocol but is not a contradiction to exercise stress testing.10

Echocardiography. Echocardiography is still the most widely used diagnostic test to check for structure and function of the heart. It uses ultrasound signals that are inaudible to the human ear.11 The ultrasound signal is reflected (i.e., echoes) whenever there is a change in the resistance to transmission of the sound beam. Thus, it is possible to create a moving image of the internal structures of the heart because the chest wall, blood, and different heart structures all reflect ultrasound differently. The echocardiogram is useful for determining ventricular dimensions and valve movements, obtaining data on the movement of the left ventricular wall and septum, estimating diastolic and systolic volumes, and viewing the motion of individual segments of the left ventricular wall during systole and diastole.

There are several different forms of echocardiography, including two-dimensional imaging, M-mode, three-dimensional, Doppler, and contrast echocardiography. M-mode echocardiography, which was the earliest form of cardiac ultrasonography, uses a stationary ultrasound beam to produce a one-dimensional or “ice-pick” view of the heart. Two-dimensional (2-D) echocardiography uses a moving ultrasound beam to produce an integrated view of the heart comprising multiple pie-shaped images. Doppler echocardiography uses ultrasound to record blood flow within the heart. Using contrast has improved the delineation of structures on the left side of the heart. Three-dimensional images of the heart can be obtained via newer transducers from a full volume three-dimensional echocardiographic image.

Transesophageal echocardiography uses a 2-D echocardiography transducer placed at the end of a flexible endoscope to obtain echocardiographic images from the esophagus.Placement of the transducer in the esophagus allows echocardiographic images of cardiac structures to be obtained from different viewpoints, rather than only from the surface of the chest.
Nuclear Cardiac Imaging. Nuclear cardiac imaging techniques involve the use of radionuclides (i.e., radioactive substances) and are essentially noninvasive. Four types of nuclear cardiology tests are commonly used: myocardial perfusion imaging, positron emission tomography (PET), and radionuclide angiography. With all four of these tests, a scintillation (gamma) camera is used to record the radiation emitted from the radionuclide. Single-photon emission computed tomography (SPECT), which uses a multiple-head camera to obtain a series of planar images over a 180- to 360-degree arc around the thorax, is the most widely used imaging technique at present.12

Myocardial perfusion imaging is used to visualize the regional distribution of blood flow. Myocardial perfusion scintigraphy uses thallium 201 or one of the newer technetium-based agents that are extracted from the blood and taken up by functioning myocardial cells. Thallium 201, an analog of potassium, is distributed to the myocardium in proportion to the magnitude of blood flow. After injection, an external detection device registers the distribution of the radioactive material. An ischemic area appears as a “cold spot” that lacks radioactive uptake. The most important application of this technique has been its use during stress testing for evaluation of ischemic heart disease.

Positron emission tomography (PET) uses positron-emitting agents to demonstrate either the perfusion or metabolic status of the myocardium. The radioisotopes used as positron emitters are the naturally occurring, small atomic weight atoms (e.g., carbon, nitrogen, oxygen) that are the predominant constituents of organic compounds such as glucose.13 During ischemia, cardiac muscle shifts from fatty acid to glucose metabolism. Thus, a radioactive tracer such as fluorodeoxyglucose can be used to distinguish a transiently dysfunctional (“stunned”) myocardium from scar tissue by showing persistent glucose metabolism in areas of reduced blood flow.

Radionuclide angiography provides actual visualization of the ventricular structures during systole and diastole and a means for evaluating ventricular function during rest and exercise stress testing. A radioisotope such as technetium-labeled albumin, which does not leave the capillaries but remains in the blood and is not bound to the myocardium, is used for this type of imaging. This type of nuclear imaging can be used to determine right and left ventricular volumes, ejection fractions, regional wall motion, and cardiac contractility. This method also is useful in the diagnosis of intracardiac shunts.

Cardiac Magnetic Resonance Imaging and Computed Tomography. The cardiac MRI creates a spatially resolved map of radio signals and, compared with x-ray–based techniques, is much safer. Cardiac MRI uses gadolinium as a contrast agent and ECG gating to prevent artifacts and blurring from periodic cardiac cycles.13 In nearly all current scanners, this is achieved by gating (triggering) the acquisition of MRI data to the R wave of the ECG. Cardiac MRI is used for quantifying the volume, mass, and function of the ventricles. It cannot be used in people with implanted pacemakers, defibrillators, or other devices.13 Recently a pacemaker with specific leads that is compatible with MRI’s has been approved by the FDA. However, there are special programming adjustments that are required prior to the MRI.

CT is an x-ray–based technique that obtains cross-sectional views of the body through rotation of the x-ray scanner around the patient. Several generations of CT technology have been developed, including conventional CT, contrast-enhanced CT, and electron beam CT. CT cardiac imaging can be performed with or without injection of a contrast agent. Noncontrast CT studies are used primarily to assess coronary artery calcification. Contrast-enhanced studies can be used to assess cardiac chambers, great cardiac vessels, and sometimes the coronary artery lumen.14 The electron beam CT, developed specifically for cardiac imaging, is a useful technique for identifying persons with or at risk for CAD. Unlike conventional CT, in which the scanner moves around the patient, in electron beam CT, only the electron beam moves.

Cardiac Catheterization and Arteriography. Cardiac catheterization is one of the most widely used invasive procedures in the assessment of CAD. Cardiac catheterization involves the passage of flexible catheters into the great vessels and chambers of the heart. In right heart catheterization, the catheter is inserted into a peripheral vein (usually the femoral) and then advanced into the right heart. The left heart catheter is inserted retrograde through a peripheral artery (usually the brachial or femoral) into the aorta and left heart. The cardiac catheterization laboratory, where the procedure is done, is equipped for viewing and recording fluoroscopic images of the heart and vessels in the chest and for measuring pressures in the heart and great vessels. It also has equipment for cardiac output studies and for obtaining samples of blood for blood gas analysis. Angiographic studies are done by injecting a radiographic contrast medium into the heart so that an outline of the moving structures can be visualized and filmed.

Coronary arteriography involves the injection of a radiographic contrast medium into the coronary arteries, permitting visualization of lesions in these vessels. It is used to identify and establish the extent of coronary artery narrowing, perform percutaneous coronary intervention (PCI) and placement of coronary artery stents, and determine appropriateness for coronary artery bypass graft surgery.15 Intracoronary physiologic measurements (Doppler ultrasonography, fractional flow reserve) can also be obtained with new sensor guide wire technology.

Coronary Atherosclerosis and the Pathogenesis of Coronary Artery Disease

Atherosclerosis is the most common cause of CAD, is slow and progressive, and can begin at a very young age in the United States and other developed countries of the world.
Atherosclerosis can affect one or all three of the major epicardial coronary arteries and their branches. Clinically significant lesions may be located anywhere in these vessels, but tend to predominate in the first several centimeters of the left anterior descending and left circumflex or the entire length of the right coronary artery. Sometimes the major secondary branches also are involved.

Coronary artery disease is commonly divided into two types of disorders: the acute coronary syndrome and chronic ischemic heart disease. The acute coronary syndrome (ACS) represents a spectrum of acute ischemic heart diseases ranging from unstable angina to myocardial infarction resulting from disruption of an atherosclerotic plaque. Chronic ischemic heart disease is characterized by recurrent and transient episodes of myocardial ischemia and stable angina that result from narrowing of a coronary artery lumen due to atherosclerosis and/or vasospasm.

**Stable versus Unstable Plaque.** There are two types of atherosclerotic lesions:

- Fixed or stable plaque, which obstructs blood flow
- Unstable/vulnerable plaque or high-risk plaque, which can rupture and cause platelet adhesion and thrombus formation

The fixed or stable plaque is commonly implicated in stable angina and the unstable plaque in unstable angina and myocardial infarction. In most cases, the myocardial ischemia underlying unstable angina, acute myocardial infarction, stroke, and, in many cases, sudden cardiac death (SCD) is precipitated by abrupt plaque changes, followed by thrombosis. The major determinants of plaque vulnerability to disruption include the size of the lipid-rich core, the stability and thickness of its fibrous cap, the presence of inflammation, and the lack of smooth muscle cells (Fig. 32.5). Plaques with a thin fibrous cap overlaying a large lipid core are at high risk for rupture.

Although plaque disruption may occur spontaneously, it is often triggered by hemodynamic factors such as blood flow characteristics and vessel tension. For example, a sudden surge of sympathetic activity with an increase in blood pressure, heart rate, force of cardiac contraction, and coronary blood flow is thought to increase the risk of plaque disruption. Indeed, many people with myocardial infarction report a trigger event, most often emotional stress or physical activity. Plaque disruption also has a diurnal variation, occurring most frequently during the first hour after arising, suggesting that physiologic factors such as surges in coronary artery tone and blood pressure may promote atherosclerotic plaque disruption and subsequent platelet deposition. It has been suggested that the sympathetic nervous system is activated on arising, resulting in changes in platelet aggregation and fibrinolytic activity that tend to favor thrombosis.

**Thrombosis and Vessel Occlusion.** Local thrombosis occurring after plaque disruption results from a complex interaction among its lipid core, smooth muscle cells, macrophages, and collagen. The lipid core provides a stimulus for platelet aggregation and thrombus formation. Both smooth muscle and foam cells in the lipid core contribute to the expression of tissue factor in unstable plaques. Once exposed to blood, tissue factor initiates the extrinsic coagulation pathway, resulting in the local generation of thrombin and deposition of fibrin.

Platelets play an important role in linking plaque disruption to acute CAD. As a part of the response to plaque disruption,
platelets adhere to the endothelium and release substances (i.e., adenosine diphosphate [ADP], thromboxane A$_2$, and thrombin) that promote further aggregation of platelets and thrombus formation. The platelet membrane, which contains glycoprotein receptors that bind fibrinogen and link platelets together, contributes to thrombus formation. Platelet adhesion and aggregation occurs in several steps. First, release of ADP, thromboxane A$_2$, and thrombin initiates the aggregation process. Second, glycoprotein IIb/IIIa receptors on the platelet surface are activated. Third, fibrinogen binds to the activated glycoprotein receptors, forming bridges between adjacent platelets.

There are two types of thrombi formed as a result of plaque disruption—white platelet-containing thrombi and red fibrin-containing thrombi. The thrombi in unstable angina have been characterized as grayish white and presumably platelet rich. Red thrombi, which develop with vessel occlusion in myocardial infarction, are rich in fibrin and red blood cells superimposed on the platelet component and completely obstruct blood flow.

**Acute Coronary Syndrome**

Acute coronary syndrome includes unstable angina, non–ST-segment elevation (non–Q-wave) myocardial infarction, and ST-segment elevation (Q-wave) myocardial infarction. Persons without ST-segment elevation on ECG are those in whom thrombotic coronary occlusion is subtotal or intermittent, whereas those with ST-segment elevation are usually found to have complete coronary occlusion on angiography, and many ultimately have Q-wave myocardial infarction.

**KEY POINTS**

**CORONARY ARTERY DISEASE**

- The term **coronary artery disease** refers to disorders of myocardial blood flow due to stable or unstable coronary atherosclerotic plaques.
- Unstable atherosclerotic plaques tend to fissure or rupture, causing platelet aggregation and potential for thrombus formation with production of a spectrum of acute coronary syndromes of increasing severity, ranging from unstable angina, to non–ST-segment elevation myocardial infarction, to ST-segment elevation myocardial infarction.
- Stable atherosclerotic plaques produce fixed obstruction of coronary blood flow with myocardial ischemia occurring during periods of increased metabolic need, such as in stable angina.

**Electrocardiographic Changes**

The classic ECG changes that occur with ACS involve T-wave inversion, ST-segment elevation, and development of an abnormal Q wave. The changes that occur may not be present immediately after the onset of symptoms and vary considerably depending on the duration of the ischemic event (acute versus evolving), its extent (subendocardial versus transmural), and its location (anterior versus inferior posterior). Because these changes usually occur over time and are seen on the ECG leads that view the involved area of the myocardium, provision for continuous and serial 12-lead ECG monitoring is indicated. The repolarization phase of the action potential (T-wave and ST segment on the ECG) is usually the first to be involved during myocardial ischemia and injury. As the involved area becomes ischemic, myocardial repolarization is altered, causing changes in the T wave. This is usually represented by T-wave inversion, although a hyperacute T-wave elevation may occur as the earliest sign of infarction. ST-segment changes occur with ischemic myocardial injury and depending on what leads are involved can indicate the lesion of interest. Normally, the ST segment of the ECG is nearly isoelectric (e.g., flat along the baseline) because all healthy myocardial cells attain the same potential during early repolarization. Acute severe ischemia reduces the resting membrane potential and shortens the duration of the action potential in the ischemic area. These changes create a voltage difference between the normal and ischemic areas of the myocardium that leads to a so-called current of injury between these regions. It is these currents of injury that are represented on the surface ECG as a deviation of the ST segment. When the acute injury is transmural, the overall ST vector is shifted in the direction of the outer epicardium, resulting in ST-segment elevation. With Q-wave infarction, abnormal Q waves and R wave loss develop because there is no depolarizing current conduction from the necrotic tissue. When the injury is confined primarily to the subendocardium, the overall ST segment is shifted toward the inner ventricular layer, resulting in an overall depression and not elevation of the ST segment.

**Serum Biomarkers**

Even though cardiac biomarkers aid clinicians in diagnosing unstable angina/non–ST-segment elevation myocardial infarction (UA/NSTEMI) in approximately one third of people, awaiting results should delay reperfusion treatment for ST-segment elevation myocardial infarction (STEMI). The 12-lead ECG should initiate reperfusion treatment since this therapy is time sensitive. Serum biomarkers for ACS include cardiac-specific troponin I (TnI) and troponin T (TnT) and creatine kinase MB (CK-MB). As the myocardial cells become necrotic, their intracellular contents begin to diffuse into the surrounding interstitium and then into the blood. The rate at which the enzymes appear in the blood depends on their intracellular location, their molecular weight, and local blood flow. For example, they may appear at an earlier-than-predicted time in patients who have undergone successful reperfusion therapy.

The troponin assays have high specificity for myocardial tissue and have become the primary biomarker tests for the diagnosis of myocardial infarction. The troponin complex, which is part of the actin filament, consists of three subunits
(i.e., troponin C [TnC], TnT, and TnI) that regulate calcium-mediated actin–myosin contractile process in striated muscle. TnI and TnT, which are present in cardiac muscle, begin to rise within 3 hours after the onset of myocardial infarction and may remain elevated for 7 to 10 days after the event. This is especially advantageous in the late diagnosis of myocardial infarction.\(^21\)

Creatine kinase is an intracellular enzyme found in muscle cells. There are three isoenzymes of CK, with the MB isoenzyme being highly specific for injury to myocardial tissue. Serum levels of CK-MB exceed normal ranges within 4 to 8 hours of myocardial injury and decline to normal within 2 to 3 days.\(^21\)

When comparing troponin and CK-MB, the troponin level identifies necrosis in cardiac muscles earlier than CK-MB. Clinicians examining cardiac biomarkers should focus on troponin levels, rather than CK-MB levels, for diagnosis and establishing the success of reperfusion.\(^21\)

Unstable Angina/Non-ST-Segment Elevation Myocardial Infarction

UA/NSTEMI is considered to be a clinical syndrome of myocardial ischemia ranging from stable angina to myocardial infarction.\(^19\) Typically, UA and NSTEMI differ in whether the ischemia is severe enough to cause sufficient myocardial damage to release detectable quantities of serum cardiac markers. Persons who have no evidence of serum markers for myocardial damage are considered to have UA, whereas a diagnosis of NSTEMI is indicated if a serum marker of myocardial injury is present.

The pathophysiology of UA/NSTEMI can be divided into five phases:

1. The development of the unstable plaque that ruptures or plaque erosion with superimposed nonocclusive thrombosis
2. An obstruction such as spasm, constriction, dysfunction, or adrenergic stimuli
3. Severe narrowing of the coronary lumen
4. Inflammation
5. Any physiological state causing ischemia related to decreased oxygen supply such as fever or hypotension\(^22\)

Inflammation can play a prominent role in plaque instability, with inflammatory cells releasing cytokines that cause the fibrous cap to become thinner and more vulnerable to rupture or erosion. The pain associated with UA/NSTEMI has a persistent and severe course and is characterized by at least one of three features:

1. It occurs at rest (or with minimal exertion), usually lasting more than 20 minutes (if not interrupted by nitroglycerin).
2. It is severe and described as frank pain and of new onset (i.e., within 1 month).
3. It is more severe, prolonged, or frequent than previously experienced.\(^22\)

Risk stratification of people presenting with UA/NSTEMI is important because the outcome can range from excellent, with little change in treatment, to NSTEMI or death, requiring aggressive treatment. UA/NSTEMI is classified by severity based on clinical history, ECG pattern, and serum biomarkers. UA/NSTEMI is classified as:

- Class I (new onset severe angina)
- Class II (angina at rest within the past month, but not within the last 48 hours)
- Class III (angina at rest within 48 hours)

The ECG pattern in UA/NSTEMI demonstrates ST-segment depression (or transient ST-segment elevation) and T-wave changes. The degree of ST-segment deviation has been shown to be an important measure of ischemia and prognosis.

ST-Segment Elevation Myocardial Infarction

Acute STEMI, also known as heart attack, is characterized by the ischemic death of myocardial tissue associated with atherosclerotic disease of the coronary arteries. The area of infarction is determined by the coronary artery that is affected and by its distribution of blood flow (Fig. 32.6). Approximately 30% to 40% of infaracts affect the right coronary artery, 40% to 50% affect the left anterior descending artery, and the remaining 15% to 20% affect the left circumflex artery.\(^21\)

Pathophysiology. The extent of the infarct depends on the location and extent of occlusion, amount of heart tissue supplied by the vessel, duration of the occlusion, metabolic needs of the affected tissue, extent of collateral circulation, and other factors such as heart rate, blood pressure, and cardiac rhythm. An infarct may involve the endocardium, myocardium, epicardium, or a combination of these. Transmural infarcts involve the full thickness of the ventricular wall and most commonly occur when there is obstruction of a single artery (Fig. 32.7). Subendocardial infarcts involve the inner one third to one half of the ventricular wall and occur more frequently in the presence of severely narrowed but still patent arteries. Most infarcts are transmural, involving the free wall of the LV and the interventricular septum.

The principal biochemical consequence of myocardial infarction is the conversion from aerobic to anaerobic metabolism with inadequate production of energy to sustain normal myocardial function. As a result, a striking loss of contractile function occurs within 60 seconds of onset.\(^21\) Changes in cell structure (i.e., glycogen depletion and mitochondrial swelling) develop within several minutes. These early changes are reversible if blood flow is restored. Although gross tissue changes are not apparent for hours after onset of myocardial infarction, the ischemic area ceases to function within a matter of minutes, and irreversible damage to cells occurs in approximately 40 minutes. Irreversible myocardial cell death (necrosis) occurs after 20 to 40 minutes of severe ischemia.\(^21\) Microvascular injury occurs in approximately 1 hour and follows irreversible cell injury. If the infarct is large enough, it depresses overall left ventricular function and pump failure ensues.
Multiple dynamic structural changes maintain cardiac function in persons with STEMI. Both the infarcted and noninfarcted areas of the ventricle undergo progressive changes in size, shape, and thickness, comprising early wall thinning, healing, hypertrophy, and dilation, collectively termed ventricular remodeling. As the nonfunctioning muscle in the infarcted area becomes thin and dilated, the muscle in the surrounding, noninfarcted area becomes thicker as it undergoes adaptive hypertrophy so it can take over the work of the muscle in the infarcted zone. However, the adaptive effect of remodeling may be overwhelmed by aneurysm formation or depression of myocardial function, causing further impairment of ventricular function.

Clinical Manifestations. STEMI may occur as an abrupt-onset event or as a progression from UA/NSTEMI. The onset of STEMI usually is abrupt, with pain as the significant symptom. The pain typically is severe and crushing, often described as being constricting, suffocating, or like “something sitting on my chest.” It usually is substernal, radiating to the left arm, neck, or jaw, although it may be experienced in other areas of the chest. Unlike that of angina, the pain associated with STEMI is more prolonged and not relieved by rest or nitroglycerin, and narcotics frequently are required. Some persons may not describe it as “pain,” but as “discomfort.” Women often experience atypical ischemic-type chest discomfort, whereas the elderly may complain of shortness of breath more frequently than chest pain.

Gastrointestinal complaints are common with STEMI. There may be a sensation of epigastric distress; nausea and vomiting may occur. These symptoms are thought to be related to the severity of the pain and vagal stimulation. The epigastric distress may be mistaken for indigestion, and the person may seek relief with antacids or other home remedies, which only delays getting medical attention. Complaints of fatigue...
and weakness, especially of the arms and legs, are common. Pain and sympathetic stimulation combine to give rise to tachycardia, anxiety, restlessness, and feelings of impending doom. A productive cough may be present with frothy, pink sputum. The skin often is pale, cool, and moist. Impairment of myocardial function may lead to hypotension and shock.

Sudden death from STEMI is death that occurs within 1 hour of symptom onset. It usually is attributed to fatal arrhythmias, which may occur without evidence of infarction. Early hospitalization after onset of symptoms greatly improves the chances of averting sudden death because appropriate resuscitation facilities are immediately available when the ventricular arrhythmia occurs.

**Management of Acute Coronary Syndrome**

Because the specific diagnosis of STEMI often is difficult to make at the time of entry into the health care system, the immediate management of UA/NSTEMI and STEMI is generally the same. The prognosis in STEMI is largely related to the occurrence of two general complications—arrhythmias and mechanical complications (pump failure). The majority of deaths from STEMI are due to the sudden development of ventricular arrhythmias. Therefore, the major elements in management of people with STEMI include

- Recognition of symptoms and prompt seeking of medical care
- Prompt deployment of an emergency medical team capable of resuscitation procedures, including defibrillation
- Expeditious transport to a hospital equipped for managing arrhythmias and providing advanced cardiac life support
- Expeditious implementation of reperfusion therapy within 60 to 90 minutes

People who experience signs and symptoms of STEMI often delay seeking treatment, despite current public information regarding the benefits of early treatment. People who delay seeking treatment in the hospital include older adults, women, African Americans, people of low socioeconomic status, people with a history of angina and/or diabetes, and people who consult a relative and/or physician.

Emergency department goals for management of ACS include identification of people who are candidates for reperfusion therapy. The history and physical examination should be conducted thoroughly, but efficiently, so as not to delay reperfusion therapy. Prior episodes of CVD, including ACS, coronary bypass surgery, or PCI, should be ascertained. Evaluation of the person’s chief complaint, typically chest pain, along with other associated symptoms is essential in differentiating ACS from other diagnoses.

For any person presenting to the emergency department with symptoms of ACS, a 12-lead ECG should be obtained and read by a physician within 10 minutes of arrival at the emergency department. The typical ECG changes may not be present immediately after the onset of symptoms, except as arrhythmias. Diagnostic ECG tracings (i.e., ST-segment elevation, prolongation of the Q wave, and inversion of the T wave) may be difficult to identify in people with STEMI who present with chest pain. Therefore serial ECG tracings should be obtained. Some added difficulties include premature ventricular contractions, which are common arrhythmias after myocardial infarction. The occurrence of other arrhythmias and conduction defects depends on the areas of the heart and conduction pathways that are included in the infarct. A new bundle branch block, particularly left bundle branch block, also serves as a criterion for STEMI and indicates a need for rapid reperfusion.

Commonly indicated treatment regimens include administration of oxygen, aspirin, nitrates, pain medications, antplatelet and anticoagulant therapy, and β-adrenergic blocking agents (beta-blockers). People with ECG evidence of infarction should receive immediate reperfusion therapy with a thrombolytic agent or PCI within 60 to 90 minutes. The importance of intensive insulin control to maintain normal blood glucose (80 to 110 mg/dL) in people who are critically ill has been supported by multiple studies. Current ACC/AHA guidelines recommend the maintenance of strict glucose control during STEMI.

Pain relief is a major objective in the treatment of STEMI. Control of pain in STEMI is accomplished through a combination of oxygen, nitrates, analgesics (e.g., morphine), and β-adrenergic blocking agents. The administration of oxygen augments the oxygen content of inspired air and increases the oxygen saturation of hemoglobin. Arterial oxygen levels may fall precipitously after STEMI, and oxygen administration helps to maintain the oxygen content of the blood perfusing the coronary circulation. In people with severe heart failure from STEMI, continuous positive-pressure ventilation or endotracheal intubation and support with mechanical ventilation may be necessary.

Nitroglycerin is given because of its vasodilating effect and ability to relieve coronary pain. The vasodilating effects of the drug decrease venous return (i.e., reduce preload) and arterial blood pressure (i.e., reduce afterload), thereby reducing oxygen consumption. Nitroglycerin may also limit infarction size and is most effective if given within 4 hours of symptom onset. Nitroglycerin usually is administered sublingually initially, after which the need for intravenous infusion is assessed. The use of intravenous nitroglycerin may be indicated for treatment of ongoing ischemic pain, control of hypertension, or management of pulmonary congestion. Nitroglycerin should not be administered to patients with severe hypotension or to patients who have received a phosphodiesterase inhibitor for erectile dysfunction within the previous 24 hours.

Although a number of analgesic agents have been used to treat the pain of STEMI, morphine is usually the drug of choice. It usually is indicated if chest pain is unrelied with oxygen and nitrates. The reduction in anxiety that accompanies the administration of morphine contributes to a decrease in restlessness and autonomic nervous system activity, with a subsequent decrease in the metabolic demands of the heart. It is commonly given intravenously because of the rapid onset of action and because the intravenous route does not elevate enzyme levels. The intravenous route also bypasses the
variable rate of absorption of subcutaneous or intramuscular sites, which often are underperfused because of the decrease in cardiac output that occurs after infarction.

β-Adrenergic blocking drugs act as antagonists that block β-receptor-mediated functions of the sympathetic nervous system and thus decrease myocardial oxygen demand by reducing heart rate and cardiac contractility, and systemic arterial blood pressure. The lengthening of diastole caused by the slower heart rate may enhance myocardial perfusion, especially to the subendocardium. Beta-blockers also alter resting myocardial membrane potentials and may decrease life-threatening ventricular arrhythmias. Because sympathetic nervous system activity increases the metabolic demands of the myocardium, oral or intravenous beta-blockers are usually administered within the first few hours after the onset of STEMI. They should not be given in STEMI caused by cocaine use because it could accentuate coronary spasm. Other relative contraindications to beta-blockers include symptomatic bradycardia, hypotension, moderate-to-severe left ventricular failure, shock, or second- or third-degree heart block.

Platelets play a major role in the thrombotic response to atherosclerotic plaque disruption; therefore, inhibition of platelet aggregation is an important aspect in the early treatment of both UA/NSTEMI and STEMI. Aspirin (i.e., acetylsalicylic acid) is the preferred antiplatelet agent for preventing platelet aggregation in persons with ACS. Aspirin, which acts by inhibiting synthesis of the prostaglandin thromboxane A₂, is thought to promote reperfusion and reduce the likelihood of rethrombosis. The actions of aspirin are related to the presence of the acetyl group, which irreversibly acetylates the critical platelet enzyme, cyclooxygenase, which is required for thromboxane A₂ synthesis. Because the action is irreversible, the effect of aspirin on platelet function lasts for the lifetime of the platelet—approximately 8 to 10 days. For patients who are unable to take aspirin because of hypersensitivity or gastrointestinal intolerance, clopidogrel may be prescribed. Clopidogrel is a thienopyridine derivative that reduces platelet aggregation by inhibiting the ADP pathway in platelets. Unlike aspirin, it has no effect on prostaglandin synthesis. Results of several studies have resulted in recommendations by the AHA for the use of clopidogrel along with aspirin for persons with UA/NSTEMI and for preprocedural loading and long-term therapy for persons undergoing PCI. Antiplatelet agents are also used in the treatment of people with ACS. Anticoagulation therapy, which targets the coagulation pathway and formation of the fibrin clot, involves the use of unfractionated and low–molecular-weight heparin. The rationale for the use of antithrombin therapy in patients with STEMI is the prevention of deep vein thrombosis, pulmonary emboli, and cerebral embolization.

Angiotensin-converting-enzyme (ACE) inhibitors are often used during the early and convalescent phases of STEMI, demonstrating a benefit in terms of decreased mortality rate. ACE inhibitors increase cardiac output and stroke volume and reduce systemic pulmonary vascular resistance as well as pulmonary capillary wedge pressure. This, in turn, reduces LV dysfunction and decreased SCD. The greatest benefit is in those people with previous infarctions, heart failure, and tachycardia. ACE inhibitors usually are started within the first 24 hours, after fibrinolytic therapy has been completed. Therapy with ACE inhibitors is usually begun with low-dose oral administration and increased steadily to full dose. Although the use of ACE inhibitors in short-term therapy for patients with UA/NSTEMI does not appear to have benefits, long-term use is helpful in preventing recurrent ischemic episodes.

Reperfusion Strategies. The term reperfusion refers to reestabilishment of blood flow through use of pharmacologic agents (fibrinolytic therapy), PCI, or coronary artery bypass grafting (CABG). All people presenting with STEMI should be assessed for reperfusion therapy as soon as possible on entry into the health care system. Time since onset of symptoms, risk of STEMI, possible risks associated with fibrinolytic therapy, and time required for transport to a skilled PCI laboratory should all be considered.

Early reperfusion (within 15 to 20 minutes) after onset of occlusion can prevent necrosis and improve myocardial perfusion in the infarct zone. Reperfusion after a longer interval can salvage some of the myocardial cells that would have died owing to longer periods of ischemia. It also may prevent the microvascular injury that occurs over a longer period. Even though much of the viable myocardium existing at the time of reflow, or reperfusion, ultimately recovers, critical abnormalities in biochemical function may persist, causing impaired ventricular function. The recovering area of the heart is often referred to as a hibernating myocardium. Because myocardial function is lost before cell death occurs, a hibernating myocardium may not be capable of sustaining life, and persons with large areas of dysfunctional myocardium may require life support until the stunned regions regain their function.

Fibrinolytic Therapy. Fibrinolytic drugs dissolve blood and platelet clots and are used to reduce mortality, limit infarct size, encourage infarct healing and myocardial remodeling, and reduce the potential for life-threatening arrhythmias. These agents interact with plasminogen to generate plasmin, which lyses fibrin clots and digests clotting factors V and VIII, prothrombin, and fibrinogen. The fibrinolytic agents include streptokinase, alteplase, reteplase, and tenecteplase-tPA. The best results occur if treatment is initiated within 30 minutes of symptom onset. The magnitude of the benefit declines after this period, but it is possible that some benefit can be achieved for up to 12 hours after the onset of pain. The person must be a low-risk candidate for complications caused by bleeding, with no intracranial hemorrhage or significant trauma within the last 3 months. The primary complication of fibrinolytic therapy is intracranial hemorrhage, which usually occurs within the first 24 hours of treatment.

Percutaneous Coronary Intervention. PCI is indicated as an early invasive procedure for patients with UA/NSTEMI who have no serious comorbidity and who have lesions amenable to PCI. PCI includes percutaneous transluminal coronary angioplasty (PTCA), stent implantation, atherectomy, and thrombectomy. The goal in PCI is to perform the procedure
Drug-eluting stents (with sirolimus, paclitaxel, zotarolimus, and everolimus) are also being used to suppress local neointimal proliferation that causes restenosis of the coronary artery. Recent clinical trials found that long-term use up to 1 year of aspirin and clopidogrel is recommended to prevent restenosis. Atherectomy (i.e., cutting of the atherosclerotic plaque with a high-speed circular blade from within the vessel) is a mechanical technique to remove atherosclerotic tissue during angioplasty. Laser angioplasty devices are also used. However, with the availability of stents, these procedures are used less frequently than in the past. Thrombectomy (removal of the thrombus) involves the use of a special catheter device to fracture the thrombus into small pieces and then pull the fracture fragments into the catheter tip so they can be propelled proximally and removed.

Coronary Artery Bypass Grafting. CABG is one of the most common surgeries performed in the world, providing relief of angina, improvement in exercise tolerance, and prolongation of life. The procedure involves revascularization of the affected myocardium by placing a saphenous vein graft between the aorta and the affected coronary artery distal to the site of occlusion or by using the internal mammary artery as a means of revascularizing the left anterior descending artery or its branches (Fig. 32.9). One to five distal anastomoses commonly are done.
Emergent or urgent CABG, as a reperfusion strategy, is indicated in situations such as failed PCI with persistent pain or hemodynamic instability, or for people who are not candidates for PCI or fibrinolytic therapy. In considering CABG as a treatment option, the risk for hospital mortality and other complications must be taken into account. Advanced age, poor left ventricular function, and the urgency with which surgery is performed increase the risk of early mortality. Serious complications, such as stroke, mediastinitis, and renal dysfunction, also increase the mortality and morbidity associated with CABG. The use of preoperative antibiotics and preemptive and postoperative administration of beta-blockers help in reducing the incidence of postoperative infection and atrial fibrillation.

CABG does not alter the progress of the CAD, and although the rate of return of angina is low for the first 5 years, about 50% of vein grafts are closed 10 years after CABG. The use of internal mammary artery grafts, however, has shown excellent late patency. Aspirin is the drug of choice for prophylaxis against early saphenous vein graft closure and is continued indefinitely. New surgical techniques in the treatment of CAD continue to evolve in an effort to reduce adverse effects of the midline sternotomy incision, cardiopulmonary bypass, and global cardioplectic arrest. Some of these include “off-pump” CABG, the development of robotic coronary bypass, and transmyocardial laser revascularization.

**Postinfarction Recovery Period**

After a myocardial infarction, there usually are three zones of tissue damage: a zone of myocardial tissue that becomes necrotic because of an absolute lack of blood flow; a surrounding zone of injured cells, some of which will recover; and an outer zone in which cells are ischemic and can be salvaged if blood flow can be reestablished (Fig. 32.10). The boundaries of these zones may change with time after the infarction and with the success of treatment measures to reestablish blood flow. If blood flow can be restored within the 20- to 40-minute time frame, loss of cell viability does not occur or is minimal. The progression of ischemic necrosis usually begins in the subendocardial area of the heart and extends through the myocardium to involve progressively more of the transmural thickness of the ischemic zone.

Myocardial cells that undergo necrosis are gradually replaced with scar tissue. An acute inflammatory response develops in the area of necrosis approximately 2 to 3 days after infarction. Thereafter, macrophages begin removing the necrotic tissue; the damaged area is gradually replaced with an ingrowth of highly vascularized granulation tissue, which gradually becomes less vascular and more fibrous. At approximately 4 to 7 days, the center of the infarcted area is soft and yellow; if rupture of the ventricle, interventricular septum, or valve structures occurs, it usually happens at this time.

Replacement of the necrotic myocardial tissue usually is complete by the seventh week. Areas of the myocardium that have been replaced with scar tissue lack the ability to contract and initiate or conduct action potentials.

**Complications.** The stages of recovery from STEMI are closely related to the size of the infarct and the changes that have taken place in the infarcted area. Fibrous scar tissue lacks the contractile, elastic, and conductive properties of normal myocardial cells; the residual effects and the complications are determined essentially by the extent and location of the injury. Among the complications of STEMI are sudden death, pericarditis, stroke, thromboemboli, and mechanical defects (e.g., mitral valve regurgitation, ventricular septal rupture, left ventricular wall rupture, and left ventricular aneurysm). Depending on its severity, myocardial infarction has the potential for compromising the pumping action of the heart. Heart failure and cardiogenic shock are dreaded complications of STEMI.

Life-threatening arrhythmias can be the first symptom of an ACS, differing in mechanism from chronic stable angina. With ACS, mechanisms may be related to reentry, abnormal automaticity, and electrolyte imbalances, particularly potassium and magnesium. Symptomatic bradycardia and heart block are also complications of ACS and are treated according to the guidelines for implantation of cardiac pacemakers and antiarrhythmic devices.

Pericarditis tends to occur in patients with large infarcts, a lower ejection fraction, and a higher occurrence of heart failure. It may appear as early as the second or third day postinfarction or up to several weeks later. This late complication, called Dressler syndrome, occurs weeks to months after STEMI and is thought to be an autoimmune response. In contrast to the pain associated with STEMI, the pain with pericarditis is sharp and stabbing and aggravated by deep inspiration and positional changes. Because of reperfusion therapy, this complication has been greatly reduced.

Acute stroke is another complication of STEMI. Risk factors for stroke after a STEMI include hypertension, older age, history of previous stroke, decreased ejection fraction, and atrial fibrillation. Thromboemboli, presenting as deep vein thrombosis or pulmonary emboli, do not present as frequently as in the past because of the use of anticoagulant therapy.
Mechanical defects result from changes that occur in the necrotic and subsequently inflamed myocardium and include rupture of the ventricular septum, papillary muscle, or free ventricular wall\(^2\) (Fig. 32.11). Partial or complete rupture of a papillary muscle is a rare but often fatal complication of transmural myocardial infarction.\(^2\) It is detected by the presence of a new systolic murmur and clinical deterioration, often with pulmonary edema. More frequently, postinfarction mitral valve regurgitation results from early ischemic dysfunction of the papillary muscle and underlying myocardium. Ventricular septal rupture occurs less frequently than in the past because of the use of reperfusion therapy. Previously thought to require surgical intervention only in symptomatic patients, surgical repair is now recommended for all people with ventricular septal rupture. Complete rupture of the free wall of the infarcted ventricle occurs in 1\% to 6\% of people and usually results in immediate death.\(^2\) It usually occurs 3 to 7 days postinfarction, usually involves the anterior wall, and is more frequent in older women. Incomplete or gradual rupture may be sealed off by the pericardium, creating a pseudoaneurysm. It requires early surgical intervention because delayed complete rupture is common.

A left ventricular aneurysm, a sharply delineated area of scar tissue that bulges paradoxically during systole (Fig. 32.12), develops in 10\% of people dying in the hospital of STEMI.\(^2\) They usually present on the anterior portion of the LV after occlusion of the left anterior descending coronary artery and become evident 4 to 8 weeks after infarct. They rarely rupture but may be associated with arterial emboli, ventricular arrhythmias, and heart failure. Surgical resection may be performed for these indications when other treatment measures fail.\(^2\)

**Cardiac Rehabilitation**

Cardiac rehabilitation programs are recommended for patients after ACS and incorporate strategies to improve adherence to medical therapies and lifestyle changes. Components of cardiac rehabilitation include exercise, nutrition, smoking cessation, psychosocial management, and education. Education is an essential component of cardiac rehabilitation programs and is often incorporated with other aspects of the program. This includes education related to exercise, nutrition, smoking cessation, and medications. Adherence to a cardiac rehabilitation program, or to any of its components, can be extremely difficult. Among the factors that influence participation and adherence are physician referral, reimbursement issues, distance and transportation, and social support.\(^2\)

An exercise program is an integral part of a cardiac rehabilitation program. It includes activities such as walking, swimming, and bicycling. These exercises involve changes in muscle length and rhythmic contractions of muscle groups. Most exercise programs are individually designed to meet each person’s physical and psychological needs. The goal of the exercise program is to increase the maximal oxygen consumption by the muscle tissues, so that these persons are able to perform more work at a lower heart rate and blood pressure.\(^2\)
In addition to exercise, cardiac risk factor modification incorporates strategies for smoking cessation, weight loss, stress reduction, and control of hypertension and diabetes (when present). Nutrition counseling has direct effects on weight, serum lipids, blood pressure, diabetes, and other factors. The choice of diet is based on beneficial effect, as well as the social and cultural needs of the patient. Dietary patterns are assessed and specific goals determined and communicated with the person. Cardiac rehabilitation programs should include an assessment of psychosocial problems, such as depression, anxiety, and social isolation. Behavioral therapy, such as stress management skills, and individual or group counseling can be provided, or referrals can be made to other experts.

**Chronic Ischemic Heart Disease**

Myocardial ischemia occurs when the ability of the coronary arteries to supply blood is inadequate to meet the metabolic demands of the heart. Limitations in coronary blood flow most commonly are the result of atherosclerosis, but vasospasm may serve as an initiating or contributing factor. There are several major types of chronic ischemic coronary artery disease: chronic stable angina, silent myocardial ischemia, variant or vasospastic angina, chest pain with normal coronary angiography, and ischemic cardiomyopathy.

**Stable Angina**

Chronic stable angina is associated with a fixed coronary obstruction that produces a disparity between coronary blood flow and metabolic demands of the myocardium. Stable angina is the initial manifestation of ischemic heart disease in approximately half of persons with CAD. Although most people with stable angina have atherosclerotic heart disease, angina does not develop in a considerable number of people with advanced coronary atherosclerosis. This probably is because of their sedentary lifestyle, the development of adequate collateral circulation, or the inability of these people to perceive pain. In many instances, myocardial infarction occurs without a history of angina.

Angina pectoris usually is precipitated by situations that increase the work demands of the heart, such as physical exertion, exposure to cold, and emotional stress. The pain typically is described as a constricting, squeezing, or suffocating sensation. It usually is steady, increasing in intensity only at the onset and end of the attack. The pain of angina commonly is located in the precordial or substernal area of the chest; it is similar to myocardial infarction in that it may radiate to the left shoulder, jaw, arm, or other areas of the chest (Fig. 32.13). In some people, the arm or shoulder pain may be confused with arthritis; in others, epigastric pain is confused with indigestion. Angina commonly is categorized according to whether it occurs with exercise, occurs during rest, is of new onset, or is of increasing severity.

Typically, chronic stable angina is provoked by exertion or emotional stress and relieved within minutes by rest or the use of nitroglycerin. A delay of more than 5 to 10 minutes before relief is obtained suggests that the symptoms are not due to ischemia or that they are due to severe ischemia. Angina that occurs at rest, is of new onset, or is increasing in intensity or duration denotes an increased risk for myocardial infarction and should be evaluated immediately using the criteria for ACS.

**Silent Myocardial Ischemia**

Silent myocardial ischemia occurs in the absence of anginal pain. The factors that cause silent myocardial ischemia appear to be the same as those responsible for angina: impaired blood flow from the effects of coronary atherosclerosis or vasospasm. Silent myocardial ischemia affects three populations—persons who are asymptomatic without other evidence of CAD, people who have had a myocardial infarct and continue to have episodes of silent ischemia, and persons with angina who also have episodes of silent ischemia. The reason for the painless episodes of ischemia is unclear. The episodes may be shorter and involve less myocardial tissue than those producing pain. Another explanation is that persons with silent angina have defects in pain threshold or pain transmission, or autonomic neuropathy with sensory denervation. There is evidence of an increased incidence of silent myocardial ischemia in persons with diabetes mellitus, probably the result of autonomic neuropathy, which is a common complication of diabetes. Silent STEMI comprises a significant proportion of all STEMIs in older adults.

**Variant (Vasospastic) Angina**

Variant angina is also known as *vasospastic* or *Prinzmetal angina*. The causes of variant angina are not completely understood, but a combination of pathologic processes may be responsible. It has been suggested that it may result from endothelial dysfunction, hyperactive sympathetic nervous system responses, defects in the handling of calcium by vascular smooth muscle, or from an alteration in nitric oxide.
Hydrate intolerance, and insulin resistance. Such as hypercholesterolemia and other dyslipidemias, carbo-angina. Metabolic abnormalities are frequently detected, myocardial infarction are normal in patients with chronic stable angina. Testing is valuable in the diagnosis of chronic stable angina, ischemic cardiomyopathy is formerly described as syndrome X. The cause of the chest pain has not been established, but is thought to reflect a problem with the microvasculature and/or increased cardiac pain perception. The alternate name microvascular angina has been suggested for this disorder.

**Chest Pain with Normal Coronary Angiography**

Exercise-induced chest pain with normal coronary angiography is frequently described as cardiac syndrome X. This disorder should not be confused with metabolic syndrome, which was formerly described as syndrome X. The cause of the chest pain has not been established, but is thought to reflect a problem with the microvasculature and/or increased cardiac pain perception. The alternate name microvascular angina has been suggested for this disorder.

**Ischemic Cardiomyopathy**

Ischemic cardiomyopathy describes CAD that results in myocardial dysfunction. This can present with symptoms of cardiomyopathy without a known history of CAD who have had multiple MIs or have occluded arteries. It is important to recognize the difference between ischemic and dilated cardiomyopathy (DCM) since ischemic cardiomyopathy may be reversed upon presentation. Ischemic cardiomyopathy caused by multiple MIs has a poor prognosis since there is greater damage compared to those who have occluded lesions that can be reversed.

**Diagnosis**

The diagnosis of angina is based on a detailed pain history, the presence of risk factors, invasive and noninvasive studies, and laboratory studies. Noncoronary causes of chest pain, such as esophageal reflux or musculoskeletal disorders, are ruled out. Noninvasive testing for chronic stable angina includes ECG, echocardiography, exercise stress testing, nuclear imaging studies, CT, and possibly cardiac MRI. Because the resting ECG is often normal, exercise testing is often used in evaluating persons with angina. Ischemia that is asymptomatic at rest is detected by precipitation of typical chest pain or ST-segment changes on the ECG. Although noninvasive testing is valuable in the diagnosis of chronic stable angina, cardiac catheterization and coronary arteriography are needed for definitive diagnosis. Serum biochemical markers for myocardial infarction are normal in patients with chronic stable angina. Metabolic abnormalities are frequently detected, such as hypercholesterolemia and other dyslipidemias, carbohydrate intolerance, and insulin resistance.

**Treatment**

Comprehensive and individualized assessment, lifestyle changes, and treatments are needed for people with chronic stable angina. The treatment goals for stable angina are directed toward symptom reduction and prevention of myocardial infarction through nonpharmacologic strategies, pharmacologic therapy, and coronary interventions. PCI relieves symptoms for people with chronic stable angina, but does not extend the life span. CABG is usually indicated in people with double- or triple-vessel disease.

Nonpharmacologic methods are aimed at symptom control and lifestyle modifications to reduce risk factors for coronary disease. They include smoking cessation in persons who smoke, stress reduction, a regular exercise program, limiting dietary intake of cholesterol and saturated fats, weight reduction if obesity is present, and avoidance of cold or other stresses that produce vasoconstriction. The goal of pharmacologic treatment of angina is to relieve ischemia and alleviate symptoms, prevent myocardial infarction and death, and improve the quality of life. Pharmacologic agents used in chronic stable angina include aspirin or clopidogrel, beta-blockers in persons without contraindications or calcium antagonists when beta-blockers are contraindicated, and ACE inhibitors in patients who also have diabetes or left ventricular systolic dysfunction (see previous discussion in section on Acute Coronary Syndrome). In patients with established CAD, including chronic stable angina, the use of lipid-lowering agents or statins is recommended, even in the presence of mild to moderate elevations of LDL cholesterol.

Nitrates, both short acting and long acting, are vasodilators used in the treatment of chronic stable angina and in silent myocardial ischemia. Nitrates exert their effect mainly through a decrease in venous return to the heart with a resultant decrease in intraventricular volume. Arterial pressure also decreases. Decreased intraventricular pressure and volume are associated with decreased wall tension and myocardial oxygen requirement. Although they are not vasodilators, beta-blocking drugs are extremely useful in management of angina associated with effort. The benefits of beta-blocking agents are due primarily to their hemodynamic effects—decreased heart rate, blood pressure, and myocardial contractility, which decrease myocardial oxygen requirements at rest and during exercise. The calcium channel–blocking drugs, also called calcium antagonists, block activated and inactivated L-type calcium channels in cardiac and smooth muscle. The therapeutic effects of the calcium channel–blocking agents result from coronary and peripheral artery dilation and from decreased myocardial metabolism associated with the decrease in myocardial contractility. Persons with variant angina usually respond to treatment with calcium antagonists.

**IN SUMMARY**

CAD is a disorder of impaired coronary blood flow, usually caused by atherosclerosis. Myocardial ischemia occurs when there is a disparity between myocardial oxygen supply and demand and can present as chronic ischemic heart disease.
The chronic ischemic heart diseases include chronic stable angina, silent myocardial ischemia, variant (vasospastic) angina, chest pain with normal angiography, and ischemic cardiomyopathy. Chronic stable angina is associated with a fixed atherosclerotic obstruction and pain that is precipitated by increased work demands on the heart and relieved by rest. Variant angina can result from spasms of the coronary arteries or other dysfunctions. Silent myocardial ischemia and ischemic cardiomyopathy occur without CAD symptoms.

**CARDIOMYOPATHIES**

After completing this section of the chapter, you should be able to meet the following objectives:

- Define the term cardiomyopathy as it relates to both the mechanical and electrical function of the myocardium.
- Differentiate among the pathophysiologic changes that occur with hypertrophic cardiomyopathy, arrhythmogenic right ventricular cardiomyopathy, dilated cardiomyopathies, and myocarditis.
- Describe the treatment strategies of both primary and secondary cardiomyopathy.

The definition and classification of the cardiomyopathies have evolved tremendously with the advance of molecular genetics. The definition and classification of cardiomyopathies were updated in an AHA scientific statement incorporating not only the advances of cardiac molecular genetics but other newly diagnosed diseases, as well as ion channelopathies.31 This scientific statement defines cardiomyopathies as

- A heterogeneous group of diseases of the myocardium associated with mechanical and/or electrical dysfunction that usually (but not invariably) exhibit inappropriate ventricular hypertrophy or dilatation and are due to a variety of causes that frequently are genetic
- Cardiomyopathies either are confined to the heart or are part of generalized systemic disorders, often leading to cardiovascular death or progressive heart failure–related disability.31

Based on this definition, the classification of cardiomyopathies is divided into two major groups: primary and secondary. The primary cardiomyopathies represent heart disorders that are confined to the myocardium, whereas the secondary cardiomyopathies represent myocardial changes that occur with a variety of systemic (multiorgan) disorders. Cardiomyopathies are usually associated with disorders related to mechanical (e.g., heart failure) or electrical (e.g., life-threatening arrhythmias) mechanisms.

**Primary Cardiomyopathies**

The primary cardiomyopathies are classified as genetic, mixed, or acquired, based on their etiology.31 The genetic cardiomyopathies include hypertrophic cardiomyopathy (HCM), arrhythmogenic right ventricular cardiomyopathy (ARVC), left ventricular noncompaction cardiomyopathy, inherited conduction system disorders, and ion channelopathies. The mixed cardiomyopathies, which include DCM, are of both genetic and nongenetic origin. Acquired cardiomyopathies include those that have their origin in the inflammatory process (e.g., myocarditis), stress (“tako-tsubo” pericarditis), or pregnancy (peripartum cardiomyopathy). In many cases, the cause is unknown, in which case it is referred to as an idiopathic cardiomyopathy.

**Genetic Cardiomyopathies**

**Hypertrophic Cardiomyopathy**. HCM is characterized by unexplained left ventricular hypertrophy with disproportionate thickening of the interventricular septum, abnormal diastolic filling, cardiac arrhythmias, and, in some cases, intermittent left ventricular outflow obstruction32 (Fig. 32.14). It is one of the most common types of cardiomyopathy, occurring in approximately 1 person in 500 of the general population.32 HCM is the most common cause of SCD in young athletes. The propensity to sudden death seems to be genetic, and implantable cardioverter defibrillators (ICDs) have proved to be lifesaving.33 Other complications that occur include atrial fibrillation, stroke, and heart failure.
HCM is an autosomal dominant heart disease caused by mutations in the genes encoding proteins of the cardiac sarcomere contractile proteins. Histologically, HCM appears as myocyte hypertrophy with myofibril disarray and increased cardiac fibrosis. Currently nine genes can be identified in genetic tests that are associated with HCM, with the β-myosin heavy chain and the myosin-binding protein C genes being the most common. More than 400 individual mutations have been identified and are unique from family to family. Some phenotypic correlates can be made from specific mutations; however, there are many exceptions, indicating that genetic modifiers and environmental factors are also important. Although HCM is inherited, it may present anywhere from early childhood to late adulthood with a broad category of manifestations and variable clinical course. The basic physiologic abnormalities in HCM are reduced left ventricular chamber size, poor compliance with reduced stroke volume that results from impaired diastolic filling, mitral regurgitation, and, in about 25% of cases, dynamic obstruction of left ventricular outflow. Clinical manifestations in the majority of the cases are asymptomatic but may include dyspnea, chest pain during exertion, exercise intolerance, syncope, and arrhythmias. Owing to massive hypertrophy, high left ventricular chamber pressure, and potentially abnormal intramural arteries, focal myocardial ischemia often develops even in the absence of CAD; thus, anginal pain is common. HCM is frequently associated with the development of left ventricular outflow obstruction during rest or exertion that is caused by systolic anterior motion of the mitral valve and contact of the mitral valve with the ventricular septum. Clinical manifestations are highly variable and may progress to end-stage heart failure with left ventricular remodeling and systolic dysfunction.

Arrhythmogenic Right Ventricular Cardiomyopathy/Dysplasia. Arrhythmogenic right ventricular cardiomyopathy/dysplasia (ARVC/D) is a heart muscle disease where fibrofatty infiltration of the right ventricular myocardium occurs causing right-sided heart failure and various rhythm disturbances, particularly ventricular tachycardia. It ranks second, after HCM, as the leading cause of SCD in young athletes. The incidence of ARVC/D varies from about 1 in 2000 to 1 in 5000, affecting men more frequently than women. It is inherited as an autosomal dominant trait in 30% to 50% of cases with eight genes identified, although some recessive forms have been identified that present somewhat differently than ARVC/D.

The disorder is characterized by progressive loss of myocytes, with partial or complete replacement of the right
ventricular muscle with fatty or fibrofatty tissue. The disorder is associated with reentrant ventricular tachyarrrhythmias of right ventricular origin that are often precipitated by exercise-induced discharge of catecholamines. Clinical manifestations are thought to present in three phases. In the early “concealed phase” individuals are generally asymptomatic but are at risk for SCD especially during exertion. In the “electrical phase,” people often present with palpitations and/or syncope. It is during this phase that right ventricular changes are identified using echocardiography. Then later “diffuse disease” people can have biventricular heart failure. Other symptoms may include abdominal pain and mental confusion.

Diagnosis of ARVC/D is based on clinical, ECG, echocardiographic, Holter monitor, cardiac MRI, signal averaged electrocardiography (SAECG), and histologic findings. Personal and family history, including first- and second-degree relatives, is important. Characteristic findings on 12-lead ECG include ventricular tachycardia with left bundle branch block pattern, T-wave inversion in the right precordial leads, and epsilon waves (small deflections just beyond the QRS complex). Right ventricular bundle branch block may also be present. Other diagnostic studies that may be used in assessing ARVC/D include signal-averaged ECG, MRI, and right ventricular angiography.

Treatment for ARVC/D is aimed at prevention of SCD. Although ARVC/D cannot be cured, the goal of treatment is to control the arrhythmias with antiarrhythmic agents. Combinations of various antiarrhythmic agents are often used. Radiofrequency ablation is used in drug-refractory cases, although it is completely successful in only 30% to 65% of cases, with multiple ablations sometimes needed. ICD placement is also indicated for drug-refractory cases and for those who have survived an SCD episode. ICD placement for others is debatable because no risk stratification system exists. Final options for treatment include ventriculotomy and heart transplantation.

**Left Ventricular Noncompaction.** Left ventricular noncompaction is a primary congenital cardiomyopathy that is thought to develop because of abnormal embryogenesis in which there is failure of trabecular compaction in the developing myocardium. It is characterized as distinct “spongy” morphologic appearance of the myocardium, primarily the apical portion of the LV. The disorder may be isolated or associated with other congenital heart diseases. Both familial and nonfamilial cases of left ventricular noncompaction have been identified, and mutations of several genes have been reported.

Signs and symptoms are primarily related to arrhythmias, embolic events, and heart failure. Diagnosis is made primarily with 2-D and color echocardiography, but cardiac MRI or left ventricular angiography may also be helpful. Treatment focuses on preventing symptoms of heart failure, arrhythmias, systemic embolic events, and sudden cardiac death.

**Ion Channelopathies.** Ion channels are pore-forming proteins that provide pathways for movement of ions across cell membranes. Diseases caused by mutations in genes encoding ion channel subunits or proteins are called ion channelopathies. In the heart, these ion channel disorders include the long QT syndrome (LQTS), short QT syndrome (SQTS), Brugada syndrome, and catecholaminergic polymorphic ventricular tachycardia.

LQTS and SQTS are caused by sodium or potassium ion channel gene mutations. LQTS, which is probably the most common of the ion channelopathies, is identified on 12-lead ECG by a prolonged QT interval. It causes a polymorphic ventricular tachycardia known as torsade de pointes. First described in 2000, the short QT syndrome is characterized by short QT interval (<330 ms) on the ECG, which can lead to ventricular tachycardia or fibrillation and SCD.

Brugada syndrome was described originally in 1992 as a clinical entity related to a sodium channel gene mutation. It is associated with SCD in young people, particularly young Southeast Asian men who experience SCD during sleep. The disorder is characterized on ECG by right bundle branch block and ST-segment elevation in the anterior pericardial leads. Catecholaminergic polymorphic ventricular tachycardia is caused by an abnormal receptor that regulates calcium release from the sarcoplasmic reticulum. It is triggered by vigorous physical activity or acute emotion and leads to syncope, polymorphic ventricular tachycardia, and SCD. The ECG of a person with Brugada syndrome is characteristic consisting of right bundle branch pattern and ST-segment elevation in V1 to V3.

**Mixed (Genetic and Nongenetic) Cardiomyopathies**

**Dilated Cardiomyopathy.** DCM is a common cause of heart failure and the leading indication for heart transplantation. About 20% to 35% have been reported as being familial in nature. Most familial cases appear to be transmitted as an autosomal dominant trait, but autosomal recessive, X-linked recessive, and mitochondrial inheritance patterns have been identified. Other causes include infections (i.e., viral, bacterial, fungal, mycobacterial, parasitic), toxins, alcoholism, chemotherapeutic agents, metals, and multiple other disorders. Often no cause is found, in which case it is often referred to as idiopathic DCM.

DCM is characterized by ventricular enlargement, a reduction in ventricular wall thickness, and impaired systolic function of one or both ventricles (Fig. 32.15). Histologically, DCM is characterized by atrophic and hypertrophic myocardial fibers and interstitial fibrosis. Cardiac myocytes, particularly those in the subendocardium, often show advanced degenerative changes. Interstitial fibrosis is present, also most prominently in the subendocardial zone. Scattered inflammatory cells may be present.

It can present in nearly any age. It is usually identified when clinical manifestations of DCM appear, such as dyspnea, orthopnea, and reduced exercise capacity. In the end stages, people with DCM often have ejection fractions of less than 25% (normal is approximately 50% to 60%). As the disease progresses, stasis of blood in the walls of the
heart chambers can lead to thrombus formation and systemic emboli. Secondary mitral valve regurgitation and abnormal cardiac rhythms are common. Death is usually due to heart failure or arrhythmias and can occur suddenly.

The treatment of DCM is directed toward relieving the symptoms of heart failure and reducing the work of the heart. Pharmacologic agents include diuretics to reduce preload, beta-blockers to reduce heart rate and myocardial oxygen demand, afterload-reducing agents to improve contractility and decrease left ventricular filling pressures, and ACE inhibitors to prevent vasoconstriction. Anticoagulants to prevent thrombus formation and antiarrhythmics may also be used. Other treatments may include a biventricular pacemaker, a biventricular ICD, and in cases that are refractory to treatment, cardiac transplantation. Removing or avoiding causative agents (if identified); avoiding myocardial depressants, including alcohol; and pacing rest with asymptomatic levels of exercise or activity are also important.

Primary Restrictive Cardiomyopathy. Restrictive cardiomyopathy is a rare form of heart muscle disease in which ventricular filling is restricted because of excessive rigidity of the ventricular walls. Restrictive cardiomyopathy can be idiopathic or associated with distinct diseases that affect the myocardium, principally radiation fibrosis, amyloidosis, sarcoidosis, or metastatic tumors. Genetics may also play a role because familial forms of restrictive cardiomyopathy have been reported.

Symptoms of restrictive cardiomyopathy include dyspnea, paroxysmal nocturnal dyspnea, orthopnea, hepatomegaly, peripheral edema, ascites, fatigue, and weakness. The manifestations of restrictive cardiomyopathy resemble those of constrictive pericarditis. In the advanced form of the disease, all the signs of heart failure are present except cardiomegaly.

Acquired Cardiomyopathies

Myocarditis (Inflammatory Cardiomyopathy). Myocarditis is the inflammation of the myocardium, but its classification, diagnosis, and treatment are complex. Clinical findings can vary greatly, from nonspecific symptoms, such as fever, myalgias, or exertional dyspnea, to hemodynamic collapse and sudden death. The incidence and prevalence of myocarditis have been difficult to ascertain because of the wide variation in clinical presentation.

Although there are a number of etiologies associated with myocarditis, it is usually caused by a viral infection, most commonly an enterovirus (coxsackievirus group B). Adenovirus and parvovirus in young children have also been identified as causative agents. Other etiologies include bacterial or fungal infections, hypersensitivity to certain drugs, and autoimmune diseases, such as systemic lupus erythematosus. Myocarditis is a frequent pathologic cardiac finding in persons with acquired immunodeficiency syndrome (AIDS), although it is unclear whether it is due to the human immunodeficiency virus infection itself or to a secondary infection.

Acute viral myocarditis appears to progress through three phases: the acute viral infection, autoimmune activation, and ongoing myocardial injury, resulting in DCM. The three phases present with varying clinical manifestations and varying indications for treatment. Phases 1 and 2 produce inflammatory responses to the initial viral infection. However, activation of the immune system in response to virus-specific antigens can also illicit inflammatory responses by the host, independent of the initial viral infection, which can lead to tissue damage in the host organism. As leukocytes, lymphocytes, and macrophages penetrate the myocardium, interstitial edema and focal myocyte necrosis lead to replacement fibrosis. It has been suggested that autoreactive T cells and host-generated cytokines, including tumor necrosis factor-α, interleukin-1, and interleukin-6, may play prominent roles in the myocardial changes that occur with myocarditis. Some cases of myocarditis progress to phase 3, which is characterized by ongoing myocardial injury that ultimately results in acute or chronic DCM, severe left ventricular failure, or life-threatening arrhythmias.

The signs and symptoms of myocarditis vary from asymptomatic to cardiogenic shock. Some persons may present with a viral syndrome such as fever, chills, nausea, vomiting, arthralgia, and myalgia, occurring up to 6 weeks before the diagnosis of myocarditis. Other persons may present with heart failure without antecedent symptoms. The onset of heart failure may be gradual or abrupt and fulminant. Emboli may occur because of the procoagulant effect of cytokines combined with decreased myocardial contractility. At times, the presentation may mimic ACS, with ST-segment and T-wave changes, positive cardiac markers, and regional wall motion abnormalities despite normal coronary arteries. People may also present with AV block or complete heart block. Viral myocarditis in children or young adults is often nonspecific, with symptoms such as fever and poor eating.
Peripartum Cardiomyopathy. Peripartum cardiomyopathy is a rare heart muscle disorder that occurs during the last trimester of pregnancy or the first 5 to 6 months after delivery. The disorder is relatively rare in the United States, but in some regions of Africa it is encountered in as much as 1% of pregnant women. The incidence is greater in African American, multiparous, or older women, and in women with twin fetuses, preeclampsia, or use of tocolytic therapy to prevent premature labor and delivery.

Although the etiology of peripartum cardiomyopathy is unknown, several causes have been proposed, including infectious, immunologic, nutritional, drug-induced, and genetic factors. Some women exhibit inflammatory cells in heart biopsies taken during the symptomatic phase of the disorder, suggesting a disordered immune response. It presents just as LV systolic dysfunction such as shortness of breath at rest and/or exertional, palpitations, edema, and orthopnea.

Diagnosis of peripartum cardiomyopathy can be challenging because symptoms that can occur normally in late pregnancy are similar to the early signs of heart failure. A joint workshop of the National Heart, Lung, and Blood Institute and the Office of Rare Diseases of the National Institutes of Health, in 1997, identified four criteria for the definition of peripartum cardiomyopathy:

1. Heart failure in the last month of pregnancy or within 5 months after delivery
2. No identifiable cause of heart failure
3. No identifiable cause of heart failure before the last month of pregnancy
4. Evidence of systolic dysfunction

Management of peripartum cardiomyopathy includes standard therapy for heart failure. However, potential teratogenic effects and excretion of drugs during breastfeeding need to be considered. The aim of therapy is to reduce fluid and salt intake, reduce preload and afterload, increase myocardial contractility, and try to prevent complications such as mortality. Prognosis depends on resolution of the heart failure. About half of women with peripartum cardiomyopathy spontaneously recover normal cardiac function; the other half are left with persistent left ventricular dysfunction or progress to overt heart failure and early death.

Stress or “Tako-Tsubo” Cardiomyopathy Stress cardiomyopathy was first described in Japan, where most cases have occurred, although cases have increased in the United States. In Japan, it was called tako-tsubo after the fishing pot with a narrow neck and wide base used to trap octopus. The term transient left ventricular apical ballooning has also been used to describe this syndrome.

Stress or tako-tsubo cardiomyopathy has been identified in the clinical setting as a transient, reversible left ventricular dysfunction in response to profound psychological or emotional stress. The syndrome occurs primarily in middle-aged women who present with acute STEMI, but who, on cardiac catheterization, have no evidence of CAD. There is, however, impaired myocardial contractility characterized by apical ballooning of the LV with hypercontractility of the basal LV.

The mechanism for myocardial stunning in stress cardiomyopathy is unclear, although some theories suggest ischemia from coronary artery spasm, microvascular spasm, hormonal predisposition, or direct myocyte injury. When catecholamine levels return to normal, the interventricular gradient resolves and left ventricular function recovers. Treatment is the same as that for heart failure, including short-term use of anti-coagulants, and most patients demonstrate rapid improvement and an excellent prognosis.

Secondary Cardiomyopathies

Secondary cardiomyopathy is a heart muscle disease in the presence of a multisystem disorder (Chart 32.2). There are numerous conditions reported to involve the myocardium. Some of these disorders produce accumulation of abnormal substances between myocytes (extracellular), whereas others produce accumulation of abnormal substances within myocytes (intracellular).

Almost 100 distinct myocardial diseases can result in the clinical features of DCM. They include cardiomyopathies associated with drugs, diabetes mellitus, muscular...
The cardiomyopathies involve both mechanical and electrical etiologies of myocardial dysfunction. They are currently identified as either primary or secondary cardiomyopathies, based on genetic or other organ system involvement. Symptoms related to most cardiomyopathies, whether primary or secondary, are those associated with heart failure and SCD. Treatments are related to symptom management and prevention of lethal arrhythmias.

The primary cardiomyopathies include genetic, mixed, or acquired types. The genetic cardiomyopathies include HCM, ARVC, left ventricular noncompaction cardiomyopathy, inherited conduction system disorders, and ion channelopathies. The mixed cardiomyopathies, which include DCM, are of both genetic and acquired origin. Acquired cardiomyopathies include those that have their origin in the inflammatory process (e.g., myocarditis), stress (tako-tsubo pericarditis), or pregnancy (peripartum cardiomyopathy). In many cases the cause is unknown, in which case it is referred to as an idiopathic cardiomyopathy.

The secondary cardiomyopathies are heart diseases in which myocardial involvement occurs as part of a generalized systemic (multiorgan) disorder. They include cardiomyopathies associated with drugs, diabetes mellitus, muscular dystrophy, autoimmune disorders, and cancer treatment agents (radiation and chemotherapeutic drugs).

**Infective Endocarditis**

Infective endocarditis (IE) is a serious and potentially life-threatening infection of the inner surface of the heart. It is characterized by colonization or invasion of the heart valves and the mural endocardium by a microbial agent, leading to the formation of bulky, friable vegetations and destruction of underlying cardiac tissues.

The incidence, demographics, and characteristics of IE have changed over the past decade. The classic picture of a...
person with preexisting RHD and community-associated bacteremia no longer represents the majority of cases of IE. More common causes now are mitral valve prolapse, congenital heart disease, prosthetic heart valves, and implantable devices such as pacemakers and defibrillators. Host factors such as neutropenia, immunodeficiency, malignancy, therapeutic immunosuppression, diabetes, and alcohol or intravenous drug use are predisposing factors. Infections of these intracardiac, arterial, and venous devices are nosocomially acquired in medical centers throughout the developed world.

Traditionally, IE has been classified on clinical grounds into acute or subacute–chronic forms, depending on the onset, etiology, and severity of the disease. Usually, the onset of acute cases is rapid and involves patients with normal cardiac valves who are either healthy and perhaps have a history of intravenous drug use, or are debilitated. Subacute–chronic cases evolve over months; these patients usually have valve abnormalities. The development of drug-resistant strains of microorganisms due to the indiscriminate use of antibiotics and an increase in the number of immunocompromised persons has made classification of acute and subacute–chronic cases more difficult.

**Etiology and Pathogenesis**

Staphylococcal infections have now emerged as the leading cause of IE, with streptococci and enterococci as the other two most common causes. Other causative agents include the so-called HACEK group (*Haemophilus* species, *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella kingae*). Also, *S. Epidermis* has been associated with implantable devices and health care–associated infections. Foremost among the factors leading to the development of IE is seeding of the blood with microbes. The portal of entry into the bloodstream may be an obvious infection, a dental or surgical procedure that causes transient bacteremia, injection of a contaminated substance directly into the blood by intravenous drug users, or an occult source in the oral cavity or gut. Endothelial injury, bacteremia, and altered hemodynamics can all incite the formation of a fibrin–platelet thrombus along the endothelial lining. The thrombus is susceptible to bacterial seeding from transient bacteremia, causing chronic monocyte activation and cytokine and tissue factor production. This results in progressive enlargement of infected valvular vegetations.

In both acute and subacute–chronic forms of IE, friable, bulky, and potentially destructive vegetative lesions form on the heart valves (Fig. 32.16). The aortic and mitral valves are the most common sites of infection, although the right heart may also be involved, particularly in intravenous drug abusers. These vegetative lesions consist of a collection of infectious organisms and cellular debris enmeshed in the fibrin strands of clotted blood. The lesions may be singular or multiple, may grow as large as several centimeters, and usually are found loosely attached to the free edges of the valve surface. The infectious loci continuously release bacteria into the bloodstream and are a source of persistent bacteremia. As the lesions grow, they cause valve destruction, leading to valvular regurgitation, ring abscesses with heart block, pericarditis, aneurysm, and valve perforation.

The intracardiac vegetative lesions also have local and distant systemic effects. The loose organization of these lesions permits the organisms and fragments of the lesions to form emboli and travel in the bloodstream, causing cerebral, systemic, or pulmonary emboli. The fragments may lodge in small blood vessels, causing small hemorrhages, abscesses, and infarction of tissue. The bacteremia also can initiate immune responses thought to be responsible for skin manifestations, polyarthritis, glomerulonephritis, and other immune disorders.

**Clinical Manifestations**

The incubation period for onset of symptoms is approximately 2 weeks or less in >80% of people. However, if the infection is *Candida* related, the incubation period can be up to 5 months. Initial symptoms of IE can include fever and signs of systemic infection, change in the character of an existing heart murmur, and evidence of embolic distribution of the vegetative lesions. In the acute form, the fever usually is spiking and accompanied by chills. In the subacute form, the fever usually is low grade, of gradual onset, and frequently accompanied by other systemic signs of inflammation, such as spleen enlargement, anorexia, malaise, and lethargy. Small petechial hemorrhages frequently result when emboli lodge in the small vessels of the skin, nail beds, and mucous membranes. Splinter hemorrhages (*i.e.*, dark red lines) under the nails of the fingers and toes are common. Cough, dyspnea, arthralgia or arthritis, diarrhea, and abdominal or flank pain may occur.
as the result of systemic emboli. Congestive heart failure can develop from valve destruction, coronary artery embolism, or myocarditis. Renal insufficiency can also develop from destruction or antimicrobial toxicities.

**Diagnosis**

IE continues to pose major challenges in diagnosis and treatment, despite advances in its epidemiology and microbiology. The diagnosis of IE cannot be made through any single test, but rather includes the use of clinical, laboratory, and echocardiographic features. The ACC/AHA recommends echocardiography in all patients who are suspected of having IE. Echocardiographic evidence of endocardial involvement is recommended by the Duke criteria, which were modified by a committee of the AHA in 2005. Three separate sets of blood cultures from three separate venipuncture sites should be obtained within 24 hours. However, the indiscriminate use of antibiotics has made identifying the causative organism much more difficult. The modified Duke criteria recommend the inclusion of Staphylococcus aureus as a major criterion, whether it is a nosocomial or a community-acquired infection as well as viridans streptococci, Streptococci bovis, and HACEK groups. A single positive blood culture for Coxiella burnetii and an anti-phase IgG antibody titer >1:800 are also considered major criteria. Negative blood cultures can occur delaying diagnosis and treatment and having a profound effect on outcome. This can occur because of prior antibiotic administration or because the causative organisms are slow growing, require special culture media, or are not readily cultured.

Echocardiography is the primary technique for detection of vegetations and cardiac complications resulting from IE and is an important tool in the diagnosis and management of disease. The ACC/AHA recommends echocardiography in all patients who are suspected of having IE. Echocardiographic evidence of endocardial involvement is now the major criterion in the modified Duke criteria. It is recommended that echocardiography be used in low initial risk or low clinical suspicion and transesophageal echocardiography is used in moderate to high clinical suspicion. High suspicion individuals include prosthetic valves, prior IE, complex congenital disease, heart failure, or new-onset heart murmur.

**Treatment**

Treatment of IE focuses on identifying and eliminating the causative microorganism, minimizing the residual cardiac effects, and treating the pathologic effect of emboli. The choice of antimicrobial therapy depends on the organism cultured and whether it occurs in a native or prosthetic valve. S. aureus, the most common cause of IE, is primarily the result of nosocomial infections from intravascular catheters, surgical wounds, and indwelling prosthetic devices. Guidelines for the prevention and management of nonvalvular cardiovascular disease–related infections are presented in the literature. The widespread emergence of multidrug-resistant organisms, including S. aureus, poses a serious challenge in the treatment of IE. In addition to antibiotic therapy, surgery may be needed for unresolved infection, severe heart failure, and significant emboli.

The majority of people with IE are cured with medical or surgical treatment. People who have had infectious endocarditis should be educated about its signs and symptoms and informed of the possibility of relapse or recurrence. Immediate medical attention should be sought if signs or symptoms recur. Prevention of IE through the use of prophylactic antibiotics is controversial. The current recommendations conclude that only a very small number of IE cases might be prevented by antibiotic prophylaxis for dental procedures. Therefore, prophylaxis is recommended only for people with previous IE, congenital heart disease (such as unrepaird cyanotic coronary heart disease repaired with prosthetic material or with residual defects), prosthetic cardiac valve, and cardiac transplantation who develop cardiac valvulopathy. It is not recommended based solely on an increased lifetime risk of acquiring IE.

**Rheumatic Heart Disease**

Rheumatic fever (RF) and rheumatic heart disease (RHD) are complications of the immune-mediated response to group A (beta-hemolytic) streptococcal (GAS) throat infection. The most serious aspect of RF is the development of chronic valvular disorders that produce permanent cardiac dysfunction and sometimes cause fatal heart failure years later. Although RF and RHD are rare in developed countries, they continue to be major health problems in underdeveloped countries, where inadequate health care, poor nutrition, and crowded living conditions still prevail.

**Pathogenesis**

Beta-hemolytic streptococci are divided into several serologic groups based on their cell wall polysaccharide antigen. Group A is further subdivided into more than 130 distinct M types, which are responsible for the vast majority of infections. The M protein best defines the virulence of the bacterium and has
been studied most intensively with regard to cross-reactivity with heart tissue.\textsuperscript{51} Although GAS causes both pharyngitis and skin (impetigo) infections, only the pharyngitis has been linked with RF and RHD.

The pathogenesis of RF still remains unclear. The time frame for development of symptoms in relation to the sore throat and the presence of antibodies to GAS strongly suggests an immunologic origin.\textsuperscript{53,54} It is thought that antibodies directed against the M protein of certain strains of streptococci cross-react with glycoprotein antigens in the heart, joints, and other tissues to produce an autoimmune response through a phenomenon called molecular mimicry.\textsuperscript{52} The onset of symptoms 2 to 3 weeks after infection and the absence of streptococci in the lesion support this belief. Although only a small percentage of persons with untreated GAS pharyngitis develop RF, the incidence of recurrence with a subsequent untreated infection is substantially greater. These observations and more recent studies suggest a genetic predisposition to the development of the disease. Also, environmental elements can affect the development of RF. It has been found that people who live in overcrowded areas, such as military barracks, have a higher incidence of RF due to the high virulence with rapid transmission.\textsuperscript{53}

**Clinical Manifestations**

RF can manifest as an acute, recurrent, or chronic disorder. The acute stage of RF includes a history of an initiating streptococcal infection and subsequent involvement of the connective tissue elements of the heart, blood vessels, joints, and subcutaneous tissues. Common to all is a lesion called the Aschoff body.\textsuperscript{52,53} which is a localized area of tissue necrosis surrounded by immune cells. The recurrent phase usually involves extension of the cardiac effects of the disease. The chronic phase of RF is characterized by permanent deformity of the heart valves and is a common cause of mitral valve stenosis. Chronic RHD usually does not appear until at least 10 years after the initial attack, sometimes decades later.

Most people with RF have a history of sore throat, headache, fever (101°F to 104°F), abdominal pain, nausea, vomiting, swollen glands (usually at the angle of the jaw), and other signs and symptoms of streptococcal infection. Other clinical manifestations associated with an acute episode of RF are related to the acute inflammatory process and the structures involved in the disease process. The course of the disease is characterized by a constellation of findings that includes migratory polyarthritis of the large joints, carditis, erythema marginatum, subcutaneous nodules, and Sydenham chorea.\textsuperscript{32,53} Laboratory markers of acute inflammation include an elevated white blood cell count, ESR, and CRP. These elevated levels of acute-phase reactants are not specific for RF but provide evidence of an acute inflammatory response.

**Polyarthritis.** Polyarthritis is the most common, and frequently the first, manifestation of RF in 75% of cases. It may be the only major criterion in adolescents and adults. The arthritis, which may range from arthralgia to disabling arthritis, most often involves the larger joints, particularly the knees and ankles, and occurs less frequently in the wrists, elbows, shoulders, and hips. It is almost always migratory, affecting one joint and then moving to another. Untreated, the arthritis lasts approximately 4 weeks. A striking feature of rheumatic arthritis is the dramatic response (usually within 48 hours) to salicylates. Arthritis usually heals completely and leaves no functional residua.

**Carditis.** Acute rheumatic carditis, which complicates the acute phase of RF, can affect the endocardium, myocardium, or pericardium. The involvement of the endocardium and valvular structures produces the permanent and disabling effects of RF. Carditis mostly manifests itself as mitral regurgitation and less commonly aortic regurgitation although all four valves can be involved. During the acute inflammatory stage of the disease, the valvular structures become red and swollen, and small vegetative lesions develop on the valve leaflets. The acute inflammatory changes gradually proceed to development of fibrous scar tissue, which tends to contract and cause deformity of the valve leaflets and shortening of the chordae tendineae. In some cases, the edges or commissures of the valve leaflets fuse together as healing occurs.

Clinical features of endocarditis/valvulitis, without a history of RHD, include the presence of an apical holosystolic murmur of mitral regurgitation or a basal early diastolic murmur of aortic regurgitation. In someone with a history of RHD, a change in the character of these murmurs or a new murmur would indicate acute rheumatic carditis.

**Subcutaneous Nodules, Erythema Marginatum, and Sydenham Chorea.** Subcutaneous nodules are hard, painless, and freely movable and usually occur over the extensor muscles of the wrist, elbow, ankle, and knee joints, ranging in size from 0.5 to 2 cm. Subcutaneous nodules rarely occur alone in RF and occur most often in association with moderate to severe carditis.

Erythema marginatum lesions are maplike, macular areas most commonly seen on the trunk or inner aspects of the upper arm and thigh, but never on the face. They occur early in the course of a rheumatic attack and tend to occur with subcutaneous nodules as well as carditis. They are transitory and disappear during the course of the disease.

Sydenham chorea is the major central nervous system manifestation of RF. It is seen most frequently in young girls and rarely occurs after 20 years of age. There typically is an insidious onset of irritability and other behavior problems. The child often is fidgety, cries easily, begins to walk clumsily, and drops things. The choreiform movements are spontaneous, rapid, purposeless, jerking movements that interfere with voluntary activities. Facial grmaces are common, and even speech may be affected. The chorea is self-limited, usually running its course within a matter of weeks or months, but recurrences are not uncommon. A previous streptococcal infection can be detected only in about two thirds of cases, making differential diagnosis more difficult.
Diagnosis

There are no specific laboratory tests that can establish a diagnosis of RF. Because of the variety of signs and symptoms, the Jones criteria for the diagnosis of RF, which were first proposed in 1944 and have undergone multiple reviews by the AHA and the World Health Organization (WHO), are designed to assist in standardizing the diagnosis of RF. The Jones criteria divide the clinical features of RF into major and minor categories, based on prevalence and specificity. The presence of two major signs (i.e., carditis, polyarthritis, chorea, erythema marginatum, and subcutaneous nodules) or one major and two minor signs (i.e., arthralgia, fever, and elevated ESR, CRP, or leukocyte count), accompanied by evidence of a preceding GAS infection, indicates a high probability of RF. The latest review, in 2004 by the WHO, proposes the diagnosis of a primary episode of RF, recurrent attacks of RF with or without RHD, rheumatic chorea, insidious onset of rheumatic carditis, and chronic RHD. The epidemiologic setting in which the diagnosis of RF is made is also considered important.

The use of echocardiography has enhanced the understanding of both acute and chronic RHD. It is useful in assessing the severity of valvular stenosis and regurgitation, the chamber size and ventricular function, and the presence and size of pleural effusions. Doppler ultrasonography may be useful in identifying cardiac lesions in persons who do not show typical signs of cardiac involvement during an attack of RF, but is not considered either a major or minor Jones criterion at this time.

Treatment and Prevention

It is important that streptococcal infections be promptly diagnosed and treated to prevent RF. The gold standard for detecting a streptococcal infection is throat culture. However, it takes 24 to 48 hours to produce a result, delaying treatment. The development of rapid tests for direct detection of GAS antigens has provided at least a partial solution for this problem. Both the throat culture and the rapid antigen tests are highly specific for GAS infection but are limited in terms of their sensitivity (e.g., the person may have a negative test result but have a streptococcal infection). A negative antigen test result should be confirmed with a throat culture when a streptococcal infection is suspected.

The presence of GAS in the upper respiratory tract can indicate either a carrier or infectious state, the latter of which can be defined by a rising antibody response. Serologic examinations for streptococcal antibodies (antistreptolysin O and antideoxyribonuclease B) are measured for retrospective confirmation of recent streptococcal infections in persons thought to have acute RF. There is, however, no single specific laboratory test result that is pathognomonic for acute or recurrent RF.

Treatment of acute RF is designed to control the acute inflammatory response and prevent cardiac complications and recurrence of the disease. During the acute phase, antibi-otics, anti-inflammatory drugs, and selective restriction of activities are prescribed. No clinical isolate of GAS is resistant to penicillin; therefore, penicillin, or another antibiotic in penicillin-sensitive patients, is the treatment of choice for GAS infection. Narrow-spectrum cephalosporins have also been given successfully but should be avoided in people who have a history of anaphylaxis to penicillin. Salicylates and corticosteroids can be used to suppress the inflammatory response, but should not be given until the diagnosis of RF is confirmed. Surgery is indicated for chronic rheumatic valve disease and is determined by the severity of the symptom or the evidence that cardiac function is significantly impaired. Procedures used include closed mitral commissurotomy, valve repair, and valve replacement.

The person who has had an attack of RF is at high risk for recurrence after subsequent GAS throat infections. Penicillin is the treatment of choice for secondary prophylaxis, but sulfadiazine or erythromycin may be used in penicillin-allergic individuals. The duration of prophylaxis depends on whether residual valvular disease is present or absent. It is recommended that persons with persistent valvular disease receive prophylaxis for at least 5 years after the last episode of acute RF or until age 21 years in the absence of carditis. It is recommended in moderate carditis to receive 10 years or until the age of 21 years of prophylaxis and 10 years or until the age of 40 years if RHD develops. Compliance with a plan for prophylactic administration of penicillin requires that the person and his or her family understand the rationale for such measures. They also need to be instructed to report possible streptococcal infections to their physicians and to inform their dentists about the disease so that they can be adequately protected during dental procedures that may traumatize the oral mucosa.

IN SUMMARY

IE involves the invasion of the endocardium by pathogens that produce vegetative lesions on the endocardial surface. The loose organization of these lesions permits the organisms and fragments of the lesions to be disseminated throughout the systemic circulation. Although several organisms can cause the condition, staphylococci have now become the leading cause of IE. Treatment of IE focuses on identifying and eliminating the causative microorganism, minimizing the residual cardiac effects, and treating the pathologic effect of emboli.

RF, which is associated with an antecedent GAS throat infection, is an important cause of heart disease. Its most serious and disabling effects result from involvement of the heart valves. Because there is no single laboratory test result, sign, or symptom that is pathognomonic for acute RF, the Jones criteria are used to establish the diagnosis during the acute stage of the disease. Primary and secondary prevention strategies focus on appropriate antibiotic therapy.
The past several decades have brought remarkable advances in the treatment and outlook for people with valvular heart disease. This is undoubtedly due to improved methods for non-invasive monitoring of ventricular function, improvement in prosthetic valves, advances in valve reconstruction procedures, and the development of useful guidelines to improve the timing of surgical interventions. However, valvular heart disease continues to produce considerable mortality and morbidity.

**Hemodynamic Derangements**

The function of the heart valves is to promote unidirectional flow of blood through the chambers of the heart. Dysfunction of the heart valves can result from a number of disorders, including congenital defects, trauma, ischemic damage, degenerative changes, and inflammation. Although any of the four heart valves can become diseased, the most commonly affected are the mitral and aortic valves. Disorders of the pulmonary and tricuspid valves are not as common, because of the low pressure in the right side of the heart.

The heart valves consist of thin leaflets of tough, flexible, endothelium-covered fibrous tissue firmly attached at the base to the fibrous valve rings. Capillaries and smooth muscle are present at the base of the leaflet but do not extend up into the valve. The leaflets of the heart valves may be injured or become diseased, the most commonly affected are the mitral and aortic valves. Disorders of the pulmonary and tricuspid valves are not as common, because of the low pressure in the right side of the heart.

The heart valves consist of thin leaflets of tough, flexible, endothelium-covered fibrous tissue firmly attached at the base to the fibrous valve rings. Capillaries and smooth muscle are present at the base of the leaflet but do not extend up into the valve. The leaflets of the heart valves may be injured or become diseased, the most commonly affected are the mitral and aortic valves. Disorders of the pulmonary and tricuspid valves are not as common, because of the low pressure in the right side of the heart.

Two types of mechanical disruptions occur with valvular heart disease: narrowing of the valve opening so it does not open properly and distortion of the valve so it does not open properly (Fig. 32.17). **Stenosis** refers to a narrowing of the valve orifice and failure of the valve leaflets to open normally. Blood flow through a normal valve can increase by five to seven times the resting volume; consequently, valvular stenosis must be severe before it causes problems. Significant narrowing of the valve orifice increases the resistance to blood flow through the valve, converting the normally smooth laminar flow to a less efficient turbulent flow.

This increases the volume and work of the chamber emptying through the narrowed valve—the left atrium in the case of mitral stenosis and the LV in aortic stenosis. Symptoms usually are noticed first during situations of increased flow, such as exercise. An incompetent or regurgitant valve permits backward flow to occur when the valve should be closed—flowing back into the LV during diastole when the aortic valve is affected and back into the left atrium during systole when the mitral valve is diseased.

The effects of valvular heart disease on cardiac function are related to alterations in blood flow across the valve and to the resultant increase in work demands on the hearts. Many valvular heart defects are characterized by heart murmurs resulting from turbulent blood flow through a diseased valve. Disorders in valve flow and heart chamber size for mitral and aortic valve disorders are illustrated in Figure 32.18.

Echocardiography, described earlier in the chapter, provides a means of visualizing valvular motion, patterns of flow, and closure patterns. Pulsed Doppler ultrasonography provides a semiquantitative or qualitative estimation of the severity of transvalvular gradients, right ventricular systolic pressure, and valvular regurgitation. Color flow Doppler provides a visual pattern of flow velocities over the anatomic 2-D or 3-D echocardiographic image. This allows for demonstration of turbulence from stenotic and regurgitant valves.

Transesophageal echocardiography with Doppler ultrasonography is used to obtain echocardiographic data when surface sound transmission is poor. It provides clearer images and allows better visualization of the AV valves and prosthetic heart valves.

**Mitral Valve Disorders**

The mitral valve controls the directional flow of blood between the left atrium and the LV. The edges or cusps of the AV valves are thinner than those of the semilunar valves; they are anchored to the papillary muscles by the chordae tendineae. During much of systole, the mitral valve is subjected to the high pressure generated by the LV as it pumps blood into the systemic circulation. During this period of increased pressure, the chordae tendineae prevent the eversion of the valve leaflets into the left atrium.
Disorders of Cardiac Function

As the resistance to flow through the valve increases, the left atrium becomes dilated and left atrial pressure rises. The increased left atrial pressure eventually is transmitted to the pulmonary venous system, causing pulmonary congestion.

The rate of flow across the valve depends on the size of the valve orifice, the driving pressure (i.e., atrial minus ventricular pressure), and the time available for flow during diastole.

**Mitral Valve Stenosis**

Mitral valve stenosis represents the incomplete opening of the mitral valve during diastole, with left atrial distention and impaired filling of the LV. Mitral valve stenosis most commonly is the result of RF. Less frequently, the defect is congenital and manifests during infancy or early childhood or in older adults related to annular calcification. Mitral valve stenosis is a continuous, progressive, lifelong disorder consisting of a slow, stable course in the early years and progressive acceleration in later years.

**Pathogenesis.** Mitral valve stenosis is characterized by fibrous replacement of valvular tissue, along with stiffness and fusion of the valve apparatus (Fig. 32.19). Typically, the mitral cusps fuse at the edges and involvement of the chordae tendineae causes shortening, which pulls the valvular structures more deeply into the ventricles. As the resistance to flow through the valve increases, the left atrium becomes dilated and left atrial pressure rises. The increased left atrial pressure eventually is transmitted to the pulmonary venous system, causing pulmonary congestion.

The rate of flow across the valve depends on the size of the valve orifice, the driving pressure (i.e., atrial minus ventricular pressure), and the time available for flow during diastole.

**KEY POINTS**

**VALVULAR HEART DISEASE**

- The heart valves determine the direction of blood flow through the heart chambers.
- Valvular heart defects exert their effects by obstructing flow of blood (stenotic valve disorders) or allowing backward flow of blood (regurgitant valve disorders).
The normal mitral valve area is 4 to 5 cm². Symptoms develop as the gradient across the valve becomes worse so that the left atrial pressure is greater than the left ventricular pressure. As the condition progresses, symptoms of decreased cardiac output occur during extreme exertion or other situations that cause tachycardia and thereby reduce diastolic filling time. In the late stages of the disease, pulmonary vascular resistance increases with the development of pulmonary hypertension; this increases the pressure against which the right heart must pump and eventually leads to right-sided heart failure.

Clinical Manifestations. The signs and symptoms of mitral valve stenosis depend on the severity of the obstruction and are related to the elevation in left atrial pressure and pulmonary congestion, decreased cardiac output owing to impaired left ventricular filling, and left atrial enlargement with development of atrial arrhythmias and mural thrombi. The symptoms are those of heart failure development including pulmonary congestion, nocturnal paroxysmal dyspnea, and orthopnea. Palpitations, chest pain, weakness, and fatigue are common complaints. Premature atrial beats, paroxysmal atrial tachycardia, and atrial fibrillation may occur as a result of distention of the left atrium. Fibrosis of the internodal and interatrial tracts, along with damage to the sinoatrial node, may occur from the rheumatic process itself. Atrial fibrillation develops in 30% to 40% of people with symptomatic mitral stenosis. Together, the fibrillation and distention predispose to mural thrombus formation. The risk of arterial embolization, particularly stroke, is significantly increased in people with atrial fibrillation.

Diagnosis. The murmur of mitral valve stenosis is heard during diastole when blood is flowing through the constricted valve orifice; it is characteristically a low-pitched, rumbling murmur, best heard at the apex of the heart. The first heart sound often is accentuated and delayed because of the increased left atrial pressure; an opening snap may precede the diastolic murmur as a result of the elevation in left atrial pressure. The 2-D and Doppler echocardiograms are most commonly used to diagnose mitral stenosis. These echocardiograms confirm the diagnosis of mitral stenosis, evaluate mitral valve morphology and hemodynamics, and measure pulmonary artery pressures. They also rule out other causes of mitral stenosis and assist in identifying the most appropriate treatment.

Treatment. Medical treatment of mitral valve stenosis is aimed at relieving signs of decreased cardiac output and pulmonary congestion. Loop diuretics are initiated to relieve some of the congestion. In atrial fibrillation, the goals are to control ventricular rate and prevent systemic embolization with anti-coagulation therapy. Antibiotic prophylaxis against recurrent RF is recommended. Surgical interventions, including balloon valvotomy, commissurotomy, and valve repair or replacement, may be used to treat degenerative and functional mitral valve disease.55-57 Balloon mitral valvotomy has been shown to be superior to closed and open commissurotomy. Although some countries continue to practice closed commissurotomy, most centers choose to perform MVR if balloon mitral valvotomy fails. The type of valve replaced depends somewhat on patient preferences. If a mechanical prosthesis is used, lifetime anticoagulation is indicated.

Mitral Valve Regurgitation
Mitral valve regurgitation is characterized by incomplete closure of the mitral valve, with the left ventricular stroke volume being divided between the forward stroke volume that moves into the aorta and the regurgitant stroke volume that moves back into the left atrium during systole (see Fig. 32.18).

Etiology and Pathogenesis. Mitral valve regurgitation can result from many processes. RHD is associated with a rigid and thickened valve that does not open or close completely. In addition to RHD, mitral regurgitation can result from rupture of the chordae tendineae or papillary muscles, papillary muscle dysfunction, or stretching of the valve structures due to dilatation of the LV or valve orifice. Mitral valve prolapse is a common cause of mitral valve regurgitation.

Acute mitral valve regurgitation may occur abruptly, such as with papillary muscle dysfunction after myocardial infarction, valve perforation in IE, or ruptured chordae tendineae in mitral valve prolapse. In acute severe mitral regurgitation, acute volume overload increases left ventricular preload, allowing a modest increase in left ventricular stroke volume. However, the forward stroke volume (that moving through the aorta into the systemic circulation) is reduced, and the regurgitant stroke volume leads to a rapid rise in left atrial pressure and pulmonary edema and decrease in cardiac output. Acute mitral valve regurgitation almost always is symptomatic. If severe, mitral valve replacement often is indicated.

The hemodynamic changes associated with chronic mitral valve regurgitation occur more slowly, allowing for recruitment of compensatory mechanisms. An increase in left ventricular end-diastolic volume permits an increase in total stroke volume, with restoration of forward flow into the aorta. Augmented preload and reduced or normal afterload (provided by unloading the LV into the left atrium) facilitate left ventricular ejection. At the same time, a gradual increase in left atrial size allows for accommodation of the regurgitant volume at a lower filling pressure.

Clinical Manifestations. The increased volume work associated with mitral regurgitation is relatively well tolerated, and many people with the disorder remain asymptomatic for many years, developing symptoms between 6 and 10 years after diagnosis. The degree of left ventricular enlargement reflects the severity of regurgitation.58 As the disorder progresses, left ventricular function becomes impaired, the forward (aortic) stroke volume decreases, and the left atrial pressure increases, with the subsequent development of pulmonary congestion. Typical symptoms are those of LV failure such as dyspnea on exertion, paroxysmal nocturnal dyspnea, and orthopnea. Surgery should be performed before the onset of these symptoms.
A characteristic feature of mitral valve regurgitation is an enlarged LV, a hyperdynamic left ventricular impulse, and a pansystolic (throughout systole) murmur. Mitral regurgitation, like mitral stenosis, predisposes to atrial fibrillation.

**Diagnosis and Treatment.** The 2-D Doppler echocardiogram is useful in mitral regurgitation to evaluate left ventricular and atrial size, measure the ejection fraction, and assist in decision making regarding surgery through assessment of the severity of the regurgitation. In some people with mitral regurgitation, preload reduction can be beneficial and may be treated with ACE inhibitors and biventricular pacing. Surgeries used in the treatment of mitral regurgitation include mitral valve repair and valve replacement with or without removal of the mitral apparatus. Mitral valve surgery is recommended in severe mitral regurgitation or symptomatic people where mitral valve regurgitation is possibly underestimated. Mitral valve repair avoids the use of anticoagulation needed with artificial valves.58

**Mitral Valve Prolapse**

Sometimes referred to as the *floppy mitral valve syndrome*, mitral valve prolapse occurs in 1% to 2.5% of the general population.57 The disorder is seen more frequently in women than in men and may have a familial basis. Familial mitral valve prolapse is transmitted as an autosomal trait, and several chromosomal loci have been identified. Although the exact cause of the disorder usually is unknown, it has been associated with Marfan syndrome, osteogenesis imperfecta, and other connective tissue disorders and with cardiac, hematologic, neuroendocrine, metabolic, and psychological disorders.

**Pathogenesis.** Pathologic findings in people with mitral valve prolapse include a myxedematous (mucinous) degeneration of mitral valve leaflets that causes them to become enlarged and floppy so that they prolapse or balloon back into the left atrium during systole53 (Fig. 32.20).

Secondary fibrotic changes reflect the stresses and injury that the ballooning movements impose on the valve. Certain forms of mitral valve prolapse may arise from disorders of the myocardium that place undue stress on the mitral valve because of abnormal movement of the ventricular wall or papillary muscle. Mitral valve prolapse may or may not cause mitral regurgitation.

**Clinical Manifestations and Diagnosis.** Most people with mitral valve prolapse are asymptomatic, and the disorder is discovered during a routine physical examination. A minority of people have chest pain mimicking angina, dyspnea, fatigue, anxiety, palpitations, and lightheadedness. Unlike angina, the chest pain often is prolonged, ill defined, and not associated with exercise or exertion. The pain has been attributed to ischemia resulting from traction of the prolapsing valve leaflets. The anxiety, palpitations, and arrhythmias may result from abnormal autonomic nervous system function that commonly accompanies the disorder. The disorder is characterized by a spectrum of auscultatory findings, ranging from a silent form to one or more midsystolic clicks followed by a late systolic or holosystolic murmur. The clicks are caused by the sudden tensing of the mitral valve apparatus as the leaflets prolapse. Two-dimensional and Doppler echocardiography are valuable noninvasive studies used to diagnose mitral valve prolapse.

**Treatment.** The treatment of mitral valve prolapse focuses on the relief of symptoms and the prevention of complications.57 People with palpitations and mild tachyarrhythmias or increased adrenergic symptoms, and those with chest discomfort, anxiety, and fatigue often respond to therapy with the β-adrenergic blocking drugs. In many cases, the cessation of stimulants such as caffeine, alcohol, and cigarettes may be sufficient to control symptoms. Transient ischemic attacks occur more frequently in persons with mitral valve prolapse. Therefore, in people with documented events who are in sinus rhythm with no atrial thrombi, daily aspirin therapy is recommended. Most people with mitral valve prolapse are encouraged to participate in regular exercise and lead a normal life. People who develop severe valve dysfunction may require valve surgery.

**Aortic Valve Disorders**

The aortic valve is located between the LV and the aorta. The aortic valve has three cusps and sometimes is referred to as the *aortic semilunar valve* because its leaflets are crescent or moon shaped (Fig. 32.17). The aortic valve has no chordae tendineae. Although their structures are similar, the cusps of the aortic valve are thicker than those of the mitral valve. The middle layer of the aortic valve is thickened near the middle, where the three leaflets meet, ensuring a tight seal. Between the thickened tissue and their free margins, the leaflets are more thin and flimsy.

An important aspect of the aortic valve is the location of the orifices for the two main coronary arteries, which are...
Aortic Valve Stenosis

Aortic valve stenosis, often referred to simply as aortic stenosis, is characterized by increased resistance to ejection of blood from the LV into the aorta (see Fig. 32.18). The most common causes of aortic valve stenosis are congenital valve malformations and acquired calcification of a normal tricuspid valve. Congenital malformations may result in unicuspid, bicuspid, or missshaped valve leaflets. Acquired aortic stenosis is usually the consequence of calcification associated with the normal “wear and tear” of either a previously normal aortic valve or congenitally bicuspid valves (with which approximately 1% of the population are born). The incidence of acquired aortic valve stenosis is 2% to 4% in adults older than 65 years of age.

Pathogenesis. The progression of calcific aortic stenosis is usually slow and varies widely among individuals. Valve changes range from mild thickening without obstruction to severe calcification with impaired leaflet motion and obstructed left ventricular outflow. Processes in the development of calcific aortic valve disease have been shown to be similar to those in CAD. Both conditions are more common in men, older persons, and persons with hypercholesteremia and both derive in part from an active inflammatory process. Early lesions of aortic sclerosis show focal subendothelial plaquelike lesions, similar to the initial phases of an atherosclerotic lesion. Aortic sclerosis is distinguished from aortic stenosis by the degree of valve impairment. In aortic sclerosis the valve leaflets are abnormally thickened, but the obstruction to outflow is minimal, whereas in aortic stenosis the functional area of the valve has decreased enough to cause measurable obstruction to outflow. Calcification of the aortic valve progresses from the base of the cusps to the leaflets. This reduces leaflet motion and effective valve area, but without commissural fusion. As calcification progresses, the leaflets become more rigid, there is worsening obstruction to left ventricular outflow, and fusion of the commissures leads to aortic stenosis.

Because aortic stenosis develops gradually, the LV has time to adapt. With increased systolic pressure from obstruction, the left ventricular wall becomes thicker, or hypertrophies, but a normal chamber volume is maintained. This increase in wall thickness can maintain a normal ejection fraction. Little hemodynamic disturbance occurs as the valve area is reduced by half its normal area (from a normal 3 to 4 cm² to 1.5 to 2 cm²). However, an additional reduction in valve area from one half to one fourth of its normal size produces severe obstruction to flow and a progressive pressure overload on the LV. At this point, the increased work of the heart begins to exceed the coronary blood flow reserve, causing both systolic and diastolic dysfunction and signs of heart failure.

Diagnosis. Aortic stenosis is usually first diagnosed with auscultation of a loud systolic ejection murmur or a single or paradoxically split second heart sound. Eventually, the classic symptoms of angina, syncope, and heart failure develop, although more subtle signs of a decrease in exercise tolerance or exertional dyspnea should be monitored closely. Angina occurs in approximately two thirds of people with advanced aortic stenosis and is similar to that observed in CAD. Dyspnea, marked fatigueability, peripheral cyanosis, and other signs of low-output heart failure usually are not prominent until late in the course of the disease. Syncope (fainting) is most commonly due to the reduced cerebral circulation that occurs during exertion when the arterial pressure declines consequent to vasodilation in the presence of a fixed cardiac output.

Echocardiography can be used to evaluate the severity of calcified aortic lesions, left ventricular size and function, degree of ventricular hypertrophy, and presence of associated valve disorders and plays a major part in decision making for aortic valve replacement. Evaluation with echocardiography is recommended as follows:

- Yearly in people with severe aortic stenosis
- Every 1 to 2 years with moderate stenosis
- Every 3 to 5 years with mild stenosis

Treatment. There is no effective medical therapy for severe aortic stenosis, although aggressive risk factor modification is indicated such as lipid-lowering and hypertensive management. In children with congenital aortic stenosis, the valve leaflets are merely fused and balloon valvulotomy may provide substantial benefit; valve replacement is the most effective treatment. Medical interventions are prescribed to relieve symptoms of heart failure for those patients who are ineligible for surgical intervention. For people with symptomatic aortic stenosis, valve replacement almost always improves symptoms.

Aortic Valve Regurgitation

Aortic valve regurgitation (or aortic regurgitation) is the result of an incompetent aortic valve that allows blood to flow back to the LV during diastole (see Fig. 32.18). As a result, the LV must increase its stroke volume to include blood entering from the lungs as well as that leaking back through the regurgitant valve.

Etiology and Pathogenesis. This defect may result from conditions that cause scarring of the valve leaflets or from enlargement of the valve orifice to the extent that the valve leaflets no longer meet. There are various causes of aortic regurgitation, including RF, idiopathic dilation of the aorta, congenital abnormalities, IE, and Marfan syndrome. Other causes include hypertension, trauma, and failure of a prosthetic valve.

Acute aortic regurgitation is characterized by the presentation of a sudden, large regurgitant volume to a LV of
normal size that has not had time to adapt to the volume overload. It is caused most commonly by disorders such as IE, trauma, or aortic dissection. Although the heart responds with use of the Frank-Starling mechanisms and an increase in heart rate, these compensatory mechanisms fail to maintain the cardiac output. As a result, there is severe elevation in left ventricular end-diastolic pressure, which is transmitted to the left atrium and pulmonary veins, culminating in pulmonary edema. A decrease in cardiac output leads to sympathetic stimulation and a resultant increase in heart rate and peripheral vascular resistance that cause the regurgitation to worsen. Death from pulmonary edema, ventricular arrhythmias, or circulatory collapse is common in severe acute aortic regurgitation.

Chronic aortic regurgitation, which usually has a gradual onset, represents a condition of combined left ventricular volume and pressure overload. As the valve deformity increases, regurgitant flow into the LV increases, diastolic blood pressure falls, and the LV progressively enlarges. Hemodynamically, the increase in left ventricular volume results in the ejection of a large stroke volume that usually is adequate to maintain the forward cardiac output until late in the course of the disease. Most persons remain asymptomatic during this compensated phase, which may last decades. The only sign for many years may be a soft systolic aortic murmur.

**Clinical Manifestations and Diagnosis.** As the disease progresses, signs and symptoms of left ventricular failure begin to appear. These include exertional dyspnea, orthopnea, and paroxysmal nocturnal dyspnea. In aortic regurgitation, failure of aortic valve closure during diastole causes an abnormal drop in diastolic pressure. Because coronary blood flow is greatest during diastole, the drop in diastolic pressure produces a decrease in coronary perfusion. Although angina is rare, it may occur when the heart rate and diastolic pressure fall to low levels. Persons with severe aortic regurgitation often complain of an uncomfortable awareness of heartbeat, particularly when lying down, and chest discomfort due to pounding of the heart against the chest wall. Tachycardia, occurring with emotional stress or exertion, may produce palpitations, head pounding, and premature ventricular contractions.

The major physical findings relate to the widening of the arterial pulse pressure. Korotkoff sounds may persist to zero, even though intraarterial pressure rarely falls below 30 mm Hg. The large stroke volume and wide pulse pressure may result in prominent carotid pulsations in the neck (Corrigan pulse), head bobbing (de Musset sign), systolic pulsations in the fingernail bed on gentle pressure (Quincke pulse), throbbing peripheral pulses, and a left ventricular impulse that causes the chest to move with each beat. The hyperkinetic pulse of more severe aortic regurgitation, called a *water-hammer pulse*, is characterized by distention and quick collapse of the artery. The turbulence of flow across the aortic valve produces a holodiastolic decrescendo murmur heard best at the left sternal border. In severe aortic regurgitation, a middiastolic rumble at the apex can be heard called the *Austin-Flint murmur*.

**Treatment.** The treatment for acute or severe chronic aortic regurgitation is aortic valve replacement. Surgery is recommended whenever patients are symptomatic, regardless of left ventricular function. In asymptomatic patients, valve replacement remains controversial. However, in patients with left ventricular systolic dysfunction or with severe left ventricular dilation, valve replacement is also recommended, even if patients are asymptomatic. Medication therapy in aortic regurgitation has been studied in clinical trials. The goal of medical therapy is to improve forward stroke volume and reduce regurgitant volume, usually through the use of afterload reducers. There is no strong indication for medical therapy based on the clinical trials. There is only a weak recommendation for afterload reduction. The first-line agent that is recommended in people with asymptomatic severe aortic regurgitation, especially in hypertensive people, is ACE inhibitors. Surgery remains the primary therapy for symptomatic severe aortic regurgitation.

**IN SUMMARY**

Dysfunction of the heart valves can result from a number of disorders, including congenital defects, trauma, ischemic heart disease, degenerative changes, and inflammation. Rheumatic endocarditis is a common cause. Valvular heart disease produces its effects through disturbances of blood flow. A stenotic valvular defect is one that causes a decrease in blood flow through a valve, resulting in impaired emptying and increased work demands on the heart chamber that empties blood across the diseased valve. A regurgitant valvular defect permits the blood flow to continue when the valve is closed. Valvular heart disorders produce blood flow turbulence and often are detected through cardiac auscultation.

**HEART DISEASE IN INFANTS AND CHILDREN**

After completing this section of the chapter, you should be able to meet the following objectives:

- Describe the flow of blood in the fetal circulation, state the function of the foramen ovale and ductus arteriosus, and describe the changes in circulatory function that occur at birth.
- Describe the anatomic defects and altered patterns of blood flow in children with atrial septal defects, ventricular septal defects, endocardial cushion defects, pulmonary stenosis, tetralogy of Fallot, patent ductus arteriosus, transposition of the great vessels, coarctation of the aorta, and single-ventricle anatomy.
- Describe the manifestations related to the acute, subacute, and convalescent phases of Kawasaki disease.
Malrotation during formation of the ventricular loop can cause various malpositions, such as dextroposition of the heart.

The embryonic heart undergoes further development as partitioning of the chambers occurs. Partitioning of the AV canal, atrium, and ventricle begins in the fourth week and essentially is complete by the fifth week. Septation of the heart begins as tissue bundles called the endocardial cushions form in the midportion of the dorsal and ventral walls of the heart in the region of the AV canal and begin to grow inward. Until septation begins, a single AV canal exists between the atria and the ventricles. As the endocardial cushions enlarge, they meet and fuse to form separate right and left AV canals (Fig. 32.22). The mitral and tricuspid valves develop in these canals. The endocardial cushions also contribute to formation of parts of the atrial and ventricular septa. Defects in endocardial cushion formation can result in atrial and ventricular septal defects, complete AV canal defects, and anomalies of the mitral and tricuspid valves.

Approximately 1 of every 115 to 125 infants born has a congenital heart defect, making this the most common form of structural birth defect. Advances in diagnostic methods and surgical treatment have greatly increased the long-term survival and outcomes for children born with congenital heart defects. Surgical correction of most defects is now possible, often within the first weeks of life, and the majority of affected children are expected to survive into adulthood.

Although thousands of infants born each year will have a congenital heart disease, other children will develop an acquired heart disease, including Kawasaki disease.

**Embryonic Development of the Heart**

The heart is the first functioning organ in the embryo. Its first pulsatile movements begin during the third week after conception. This early development of the heart is essential to the rapidly growing embryo as a means of circulating nutrients and removing waste products. Most of the development of the heart and blood vessels occurs between the third and eighth weeks of embryonic life.

The developing heart begins as two endothelial tubes that fuse into a single tubular structure. The early heart structures develop as the tubular heart elongates and forms alternating dilations and constrictions. A single atrium and ventricle along with the bulbus cordis develop first (Fig. 32.21). This is followed by formation of the truncus arteriosus and the sinus venosus, a large venous sinus that receives blood from the embryo and developing placenta. The early pulsatile movements of the heart begin in the sinus venosus and move blood out of the heart by way of the bulbus cordis, truncus arteriosus, and aortic arches.

A differential growth rate in the early cardiac structures, along with fixation of the heart at the venous and arterial ends, causes the tubular heart to bend over on itself. As the heart bends, the atrium and the sinus venosus come to lie behind the bulbus cordis, truncus arteriosus, and ventricle. This looping of the primitive heart results in the heart’s alignment in the left side of the chest with the atrium located behind the ventricle.
Compartmentalization of the ventricles begins with the growth of the interventricular septum from the floor of the ventricle moving upward toward the endocardial cushions. Fusion of the endocardial cushions with the interventricular septum usually is completed by the end of the seventh week.

Partitioning of the atrial septum is more complex and occurs in two stages, beginning with the formation of a thin, crescent-shaped membrane called the septum primum that emerges from the anterosuperior portion of the heart and grows toward the endocardial cushions, leaving an opening called the foramen primum between its lower edge and the endocardial cushions. A second membrane, called septum secundum, also begins to grow from the upper wall of the atrium on the right side of the septum primum. As this membrane grows toward the endocardial cushions, it gradually overlaps an opening in the upper part of the septum primum, forming an oval opening with a flap-type valve called the foramen ovale (see Fig. 32.22). The upper part of the septum primum gradually disappears, with the remaining part becoming the valve of the foramen ovale. The foramen ovale forms a communicating channel between the two upper chambers of the heart. This opening, which typically closes shortly after birth, allows blood from the umbilical vein to pass directly into the left heart, bypassing the lungs.

To complete the transformation into a four-chambered heart, provision must be made for separating the blood pumped from the right side of the heart, which is to be diverted into the pulmonary circulation, from the blood pumped from the left side of the heart, which is to be pumped to the systemic circulation. This separation of blood flow is accomplished by developmental changes in the outflow channels of the tubular heart, the bulbus cordis and the truncus arteriosus, which undergo spiral twisting and vertical partitioning (Fig. 32.23). As these vessels spiral and divide, the aorta takes up position posterior to and to the right of the pulmonary artery. Impaired spiraling during this stage of development can lead to defects such as transposition of the great vessels.

In the process of forming a separate pulmonary trunk and aorta, a vessel called the duc tus arteriosus develops. This vessel, which connects the pulmonary artery and the aorta, allows blood entering the pulmonary trunk to be shunted into the aorta as a means of bypassing the lungs. Like the foramen ovale, the duc tus arteriosus usually closes shortly after birth.62

**Fetal and Perinatal Circulation**

The fetal circulation is different anatomically and physiologically from the postnatal circulation. Blood flow in the fetal circulation occurs in parallel rather than in series, with the right ventricle delivering most of its output to the placenta for oxygen uptake and the LV pumping blood to the heart, brain, and primarily upper body of the fetus.61 Before birth, oxygenation of blood occurs through the placenta, and after birth, it occurs through the lungs. The fetus is maintained in a low-oxygen state (PO2 30 to 35 mm Hg; hemoglobin O2 saturation 60% to 70%). To compensate, fetal cardiac output is higher than at any other time in life (400 to 500 mL/kg/minute), and fetal hemoglobin has a higher affinity for oxygen.63 Also, the pulmonary vessels in the fetus are markedly constricted because of the fluid-filled lungs and the heightened hypoxic stimulus for vasoconstriction that is present in the fetus. As a result, blood flow through the lungs is less than at any other time in life.

In the fetus, blood enters the circulation through the umbilical vein and returns to the placenta through the two umbilical arteries (Fig. 32.24). A vessel called the duc tus venosus allows the majority of blood from the umbilical vein to bypass the hepatic circulation and pass directly into the inferior vena cava. From the inferior vena cava, blood flows into the right atrium, where approximately 40% of the blood volume moves through the foramen ovale into the left atrium. It then passes into the LV and is ejected into the ascending aorta to perfuse the head and upper extremities. In this way, the best-oxygenated blood from the placenta is used to perfuse the brain. At the same time, venous blood from the head and upper extremities returns to the right side of the heart through the superior vena cava, moves into the right ventricle, and is ejected into the pulmonary artery. Because of the very high pulmonary vascular resistance that is present, almost 90% of blood ejected into the pulmonary artery gets diverted through
the ductus arteriosus into the descending aorta. This blood perfuses the lower extremities and is returned to the placenta by the umbilical arteries.

At birth, the infant takes its first breath and switches from placental to pulmonary oxygenation of the blood. The most dramatic alterations in the circulation after birth are the elimination of the low-resistance placental vascular bed and the marked pulmonary vasodilation that is produced by initiation of ventilation. Within minutes of birth, pulmonary blood flow increases from 35 mL/kg/minute to 160 to 200 mL/kg/minute. The pressure in the pulmonary circulation and the flow increases from 35 mL/kg/minute to 160 to 200 mL/kg/minute. Within minutes of birth, pulmonary blood flow increases from 35 mL/kg/minute to 160 to 200 mL/kg/minute. Within minutes of birth, pulmonary blood flow increases from 35 mL/kg/minute to 160 to 200 mL/kg/minute. The resultant decrease in right atrial pressure and increase in left ventricular pressure. Cord clamping and removal of the low-resistance placental circulation produce an increase in systemic vascular resistance and a resultant increase in left ventricular pressure. The resultant decrease in right atrial pressure and increase in left atrial pressure produce closure of the foramen ovale flap valve. Reversal of the fetal hypoxemic state also produces constriction of ductal smooth muscle, contributing to closure of the ductus arteriosus by 72 hours post birth. After the initial precipitous fall in pulmonary vascular resistance, a more gradual decrease in pulmonary vascular resistance is related to regression of the medial smooth muscle layer in the pulmonary arteries. During the first 2 to 9 weeks of life, gradual thinning of the smooth muscle layer results in further decreases in pulmonary vascular resistance. By the time a healthy, term infant is several weeks old, the pulmonary vascular resistance has fallen to adult levels.

Several factors, including alveolar hypoxia, prematurity, lung disease, and congenital heart defects, may affect postnatal pulmonary vascular development. Alveolar hypoxia is one of the most potent stimuli of pulmonary vasoconstriction and pulmonary hypertension in the neonate. During this period, the pulmonary arteries remain highly reactive and can constrict in response to hypoxia, acidosis, hyperinflation of the alveoli, and hypothermia. Thus, hypoxia during the first days of life may delay or prevent the normal decrease in pulmonary vascular resistance.

Much of the development of the smooth muscle layer in the pulmonary arterioles occurs during late gestation; as a result, infants born prematurely have less medial smooth muscle. These infants follow the same pattern of smooth muscle regression, but because less muscle exists, the muscle layer may regress in a shorter time. The pulmonary vascular smooth muscle in premature infants also may be less responsive to hypoxia. For these reasons, a premature infant may demonstrate a larger decrease in pulmonary vascular resistance and a resultant shunting of blood from the aorta through the ductus arteriosus to the pulmonary artery within hours of birth.

### Congenital Heart Defects

The major development of the fetal heart occurs between the fourth and seventh weeks of gestation, and most congenital heart defects arise during this time. Most congenital heart defects are thought to be multifactorial in origin, resulting from an interaction between a genetic predisposition toward development of a heart defect and environmental influences.

Knowledge about the genetic basis of congenital heart defects has grown dramatically in recent years. This area of research is particularly important as more individuals with congenital heart disease survive into adulthood and consider having children of their own. Recent knowledge suggests that the genetic contribution to congenital heart disease has been underestimated in the past. Some heart defects, such as aortic stenosis, atrial septal defect of the secundum type, pulmonary valve stenosis, tetralogy of Fallot, and certain ventricular septal defects, have a stronger familial predisposition than others.

Chromosomal abnormalities are also associated with congenital heart defects, as much as 30% of children with congenital heart disease have an associated chromosomal abnormality. Heart disease is found in nearly 100% of children with trisomy 18; 50% of those with trisomy 21; and 35% of those with Turner syndrome. Another syndrome that commonly include cardiac malformations are Williams syndrome (7q11.23 microdeletion), which is associated with supravalvar aortic and pulmonary stenoses.62

As much as 30% of congenital cardiac defects may be attributable to identifiable and potentially modifiable risk factors, including teratogenic influences, and adverse maternal conditions such as febrile illnesses, systemic lupus erythematosus, diabetes mellitus, maternal alcohol ingestion, and treatment with...
anticonvulsant drugs, retinoids, lithium, and other prescription or nonprescription drugs. Proper prenatal care, especially periconceptive multivitamin intake with folic acid, may reduce the risk of cardiac disease in the fetus.

Pathophysiology

Congenital heart defects produce their effects mainly through abnormal shunting of blood, production of cyanosis, and disruption of pulmonary blood flow.

Abnormal Shunting of Blood. Shunting of blood refers to the diversion of blood flow from one system to the other—from the arterial to the venous system (i.e., left-to-right shunt) or from the venous to the arterial system (i.e., right-to-left shunt). The shunting of blood in congenital heart defects is determined by the presence, position, and size of an abnormal opening between the right and left circulations and the degree of resistance to flow through the opening.

The vascular resistance of the systemic and pulmonary circulations influences the direction of shunting. Because of the high pulmonary vascular resistance in the neonate, atrial and ventricular septal defects usually do not produce significant shunt or symptoms during the first weeks of life.

As the pulmonary vascular smooth muscle regresses in the neonate, the resistance in the pulmonary circulation falls below that of the systemic circulation; in uncomplicated atrial or ventricular septal defects, blood shunts from the left side of the heart to the right. In more complicated ventricular septal defects, increased resistance to outflow may affect the pattern of shunting. For example, defects that increase resistance to aortic outflow (e.g., aortic valve stenosis, coarctation of the aorta, hypoplastic left heart syndrome) increase left-to-right shunting, and defects that obstruct pulmonary outflow (e.g., pulmonary valve stenosis, tetralogy of Fallot) increase right-to-left shunting. Crying, defecating, or even the stress of feeding may increase pulmonary vascular resistance and cause an increase in right-to-left shunting and cyanosis in infants with septal defects.

Cyanotic versus Acyanotic Disorders Congenital heart diseases are commonly divided into two categories: acyanotic and cyanotic. Defects that result in a left-to-right shunt are usually categorized as acyanotic disorders because they do not compromise oxygenation of blood in the pulmonary circulation.

Defects that produce shunting of blood from the right to the left side of the heart or result in obstruction of pulmonary blood flow are categorized as cyanotic disorders. Cyanosis, a bluish color of the skin, most notable in the nail beds and mucous membranes, develops when sufficient deoxygenated blood from the right side of the heart mixes with oxygenated blood in the left side of the heart. Abnormal color becomes obvious when the oxygen saturation falls below 80% in the capillaries (equal to 5 g of deoxygenated hemoglobin).

A right-to-left shunt results in deoxygenated blood moving from the right side of the heart to the left side and then being ejected into the systemic circulation. With a left-to-right shunt, oxygenated blood intended for ejection into the systemic circulation is recirculated through the right side of the heart and back through the lungs. This increased volume distends the right side of the heart and pulmonary circulation and increases the workload placed on the right ventricle. A child with a defect that causes left-to-right shunting usually has an enlarged right side of the heart and pulmonary blood vessels. Of the congenital defects discussed in this chapter, patent ductus arteriosus, atrial and ventricular septal defects, endocardial cushion defects, pulmonary valve stenosis, and coarctation of the aorta are considered defects with little or no cyanosis; tetralogy of Fallot, transposition of the great vessels, and single-ventricle anatomy are considered defects with cyanosis.

Disruption of Pulmonary Blood Flow. Many of the complications of congenital heart disorders result from a decrease or an increase in pulmonary blood flow. Defects that reduce pulmonary blood flow (e.g., pulmonary stenosis) typically cause symptoms of fatigue, dyspnea, and failure to thrive. In contrast to the arterioles in the systemic circulation, the arterioles in the pulmonary circulation are normally thin-walled vessels that can accommodate the various levels of stroke volume that are ejected from the right heart. The thinning of the pulmonary vessels occurs during the first weeks after birth, during which the vessel media thin and pulmonary vascular resistance decreases. In a term infant who has a congenital heart defect that produces markedly increased pulmonary blood flow (e.g., ventricular septal defect), the increased flow stimulates pulmonary vasoconstriction and delays or reduces the normal involutional thinning of the small pulmonary arterioles. In most cases during early infancy, pulmonary vascular resistance is only slightly elevated, and the major contribution to pulmonary hypertension is the increased blood flow. However, in some infants with a large right-to-left shunt, the pulmonary vascular resistance never decreases.

Congenital heart defects that persistently increase pulmonary blood flow or pulmonary vascular resistance have the potential of causing pulmonary hypertension and producing irreversible pathologic changes in the pulmonary vasculature. When shunting of systemic blood flow into the pulmonary circulation threatens permanent injury to the pulmonary vessels, a surgical procedure should be done to reduce the flow temporarily or permanently. Pulmonary artery banding consists of placing a constrictive band around the main pulmonary artery, thereby increasing resistance to outflow from the right ventricle. The banding technique is a temporary measure to alleviate symptoms and protect the pulmonary vasculature in anticipation of later surgical repair of the defect.

Manifestations and Treatment

It is increasingly common for heart defects to be diagnosed prenatally. In this case, the infant can be evaluated shortly after birth to confirm the diagnosis and develop a treatment plan. Reliable diagnostic images of the fetal heart can be obtained as early as 16 weeks of gestation, and research using transvaginal
ultrasonography is under way to view the heart even earlier. Among the disorders that can be diagnosed with certainty by fetal echocardiography are AV septal defects, hypoplastic left heart syndrome, aortic valve stenosis, HCM, pulmonic valve stenosis, and transposition of the great arteries. Disorders that result in an abnormal four-chamber view, an image typically obtained during routine prenatal ultrasonography, are the most likely to be detected.67

In the postnatal period, congenital heart defects may present with numerous signs and symptoms. Over 40 different types of congenital heart defects have been described, and even individual lesions can vary along a spectrum of severity; therefore, there is no standard presentation for infants and children with congenital heart disease. Some defects, such as patent ductus arteriosus and small ventricular septal defects, close spontaneously. In other, less severe defects, there may be no obvious signs and symptoms, and the disorder may be discovered during a routine health examination. Cyanosis, pulmonary congestion, cardiac failure, and decreased peripheral perfusion are the chief concerns in children with more severe defects. Such defects often cause problems immediately after birth or early in infancy. The child may exhibit cyanosis, respiratory difficulty, and fatigueability and is likely to have difficulty with feeding and failure to thrive. A generalized cyanosis that persists longer than 3 hours after birth suggests congenital heart disease.68

An oxygen challenge (administration of 100% oxygen for 10 minutes) can help to determine whether congenital heart disease is present in a cyanotic newborn. An arterial blood sample is taken during this time. If the partial pressure of oxygen (PO2) is greater than 250 mm Hg, cyanotic heart disease can be ruled out; if the PO2 is 160 to 250 mm Hg, heart disease is unlikely; failure of the PO2 to rise to these levels is strongly suggestive of cyanotic heart disease.66 Because infant cyanosis may appear as duskyness, it is important to assess the color of the mucous membranes, fingernails, toenails, tongue, and lips. Pulmonary congestion in the infant causes an increase in respiratory rate, orthopnea, grunting, wheezing, coughing, and crackles. A chest radiograph can quickly differentiate infants who have reduced pulmonary vascular markings (densities) from those who have normal or increased markings. The infant whose peripheral perfusion is markedly decreased may be in a shocklike state.

Heart failure manifests itself as tachypnea or dyspnea at rest or on exertion. For the infant, this most commonly occurs during feeding. Recurrent respiratory infections and excessive sweating may also be reported. Also, syncope or near syncope can occur. Growth failure results from unresolved heart failure.45 The treatment plan usually includes supportive therapy (e.g., digoxin, diuretics, and feeding supplementation) designed to help the infant compensate for the limitations in cardiac reserve and to prevent complications. Surgical intervention often is required for severe defects. It may be done in the early weeks of life or, conditions permitting, delayed until the child is older. Children with structural congenital heart disease and those who have had corrective surgery may have a higher-than-expected risk for development of IE.

Prophylactic antibiotic therapy before dental procedures or other periods of increased risk for bacteremia is suggested for children with

1. Unrepaired cyanotic heart disease, including those with palliative shunts and conduits
2. Completely repaired congenital heart disease with prosthetic material or device, whether placed by surgery or catheter intervention, during the first 6 months after the procedure
3. Repaired congenital heart disease with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization) and prior IE51,70,71

**Types of Defects**

Congenital heart defects can affect almost any of the cardiac structures or central blood vessels. Defects include communication between heart chambers, interrupted development of the heart chambers or valve structures, malposition of heart chambers and great vessels, and altered closure of fetal communication channels. The particular defect reflects the embryo’s stage of development at the time it occurred. It is common for multiple defects to be present in one child and for some congenital heart disorders, such as tetralogy of Fallot, to involve several defects.

The development of the heart is simultaneous and sequential; a heart defect may reflect the multiple developmental events that were occurring simultaneously or sequentially. Most infants who have a congenital heart defect usually do not have a major problem during infancy. Only about one third of infants who are born with anomalies have a disease state that is critical. Over 40 types of defects have been identified, the most common being ventricular septal defects (~28% to 42%).68

**Patent Ductus Arteriosus.** The ductus arteriosus plays a vital role in diverting blood from the right side of the heart and away from the lungs to the systemic circulation during fetal life (Fig. 32.25G). With the onset of spontaneous respiration after birth, muscular constriction of the ductal tissue typically closes this vessel. The initiating step of ductal closure in the healthy infant is believed to be the sharp increase in arterial oxygen saturation and subsequent fall in pulmonary vascular resistance after birth. Additional factors that are thought to contribute to ductal closure are a fall in endogenous levels of prostaglandins and adenosine and the release of vasoactive substances. After constriction, the lumen of the ductus becomes permanently sealed with fibrous tissue within 2 to 3 weeks.

For 90% of full-term infants, the ductus is functionally closed by 48 hours of age.72 Full-term infants with abnormalities of circulation or ventilation and premature infants are those most likely to exhibit persistent patency of the ductus arteriosus. Arterial oxygenation, circulating prostaglandins, genetic predetermination, and other, unknown factors interact
to determine the mechanism of ductal closure. Circulating prostaglandin levels are directly related to gestational age, and the incidence of patent ductus arteriosus in infants with birth weights less than 1000 g may be as high as 50%. Persistent patency of the ductus arteriosus is defined as a duct that remains open beyond 3 months in the full-term infant. The size of the persistent ductus and the difference between the systemic and pulmonary vascular resistance determine its clinical manifestations. Blood typically shunts across the ductus from the higher-pressure left side (systemic circulation) to the lower-pressure right side (pulmonary circulation). A murmur is typically detected within days or weeks of birth. The murmur is loudest at the second left intercostal space, is continuous through systole and diastole, and has a characteristic “machinery” sound. A widened pulse pressure is common due to the continuous runoff of aortic blood into the pulmonary artery. Diagnostic methods include chest radiography and echocardiography. There are increased pulmonary markings on chest radiography and enlargement of the left heart from the increased pulmonary venous return if it is a larger shunt. Chest x-rays are normal in small shunts. Echocardiography is used to determine the presence, size, direction (i.e., left to right or right to left), and physical consequences of the shunt.

An untreated patent ductus can result in important long-term complications that may include congestive heart failure, IE, pulmonary vascular disease, aneurysm formation, thromboembolism, and calcification. The potential risk of complications and the extremely low procedural morbidity and mortality justify closure of a patent arterial ductus even when the shunt is small. In the premature infant, a patent ductus can produce respiratory distress and impede weaning from mechanical ventilation. Indomethacin, an inhibitor of prostaglandin synthesis, has proven effective in up to 79% of premature infants. There has also been some success with the use of ibuprofen; however, the long-term effects on chronic lung disease and pulmonary hypertension are still unknown.

When this medical management fails, surgical intervention is recommended. In the full-term infant or older child, closure can be achieved with either surgical ligation or device occlusion. Surgery typically involves a small left thoracotomy or thorascopic approach that allows ligation of the vessel. Implantable devices, most commonly coils, have allowed successful ductus closure to be done in the catheterization laboratory on an outpatient basis. The anatomy of the ductus and the size of the patient are key determinants of the applicability of this technique.

Although closure of a patent ductus is uniformly recommended when it is present as an isolated lesion, deliberate maintenance of ductal patency can be a lifesaving therapy for children with complex forms of congenital heart disease who have ductal-dependent pulmonary or systemic blood flow or those with obligatory mixing of the arterial and venous circulations (i.e., transposition of the great arteries). Intravenous infusion of prostaglandin E1 has proved extremely effective in maintaining ductal patency or reopening the ductus in newborns. Today, this therapy is routinely administered to newborns with suspected congenital heart defects until they can be transported to a specialized center where a diagnosis can be confirmed.

Atrial Septal Defects. Any persistent opening that allows shunting of blood across the atrial septum is considered an atrial septal defect. The defect may be single or multiple and vary from a small, asymptomatic opening to a large, symptomatic opening. The typology of the defect is determined by its position and may include a secundum atrial defect (the most common form), an ostium primum defect, a sinus venosus defect, or a patent foramen ovale (see Fig. 32.25A). The defect occurs more frequently in girls than boys, as much as 2:1. As much as 50% of children with congenital heart disorders have an atrial septal defect as a part of their diagnosis.

Many atrial septal defects are asymptomatic and discovered inadvertently during a routine physical examination at a few years of age. Intracardiac shunting is usually from left to right and may increase with age as the right ventricle becomes more compliant. In most cases there is a moderate shunt resulting in dilatation of the right heart chambers and overperfusion of the pulmonary circulation. The increased volume of blood that must be ejected from the right heart prolongs closure of the pulmonary valve and produces a separation (fixed splitting) of the aortic and pulmonary components of the second heart sound. Children with undiagnosed atrial defects are at risk for pulmonary vascular disease, although this is a rare occurrence before 20 years of age. Rarely, infants with a large shunt may develop congestive heart failure and failure to thrive, prompting early closure of the defect.

Atrial septal defects that measure 8 mm or more are unlikely to undergo spontaneous closure. Smaller defects may be observed for spontaneous closure in the young child. However, surgical or transcatheter closure is recommended in children with persistent defects to reduce the long-term risk of pulmonary vascular disease and atrial arrhythmias. Both transcatheter device and surgical closure are effective and of low risk. Use of the transcatheter approach is determined by the position and size of the defect. Transcatheter device closure has been particularly effective for small to medium-sized secundum septal defects and patent foramen ovale. Sinus venosus defects, which are frequently associated with partial anomalous pulmonary venous return and ostium primum defects, require surgical closure. Surgery requires the use of cardiopulmonary bypass and mild hypothermia. Most defects are effectively closed using the patient’s native septal tissue or a pericardial or synthetic patch. There is a very low incidence of residual sequelae or need for reintervention if closure occurred during the first two decades of life.

Ventricular Septal Defects. A ventricular septal defect is an opening in the ventricular septum that results from an incomplete separation of the ventricles during early fetal development (see Fig. 32.25B). These defects may be single or multiple and may occur in any position along the ventricular
Ventricular septal defects are the most common form of congenital heart defect, accounting for 28% to 42% of congenital heart disorders. Distribution between boys and girls is relatively even. Ventricular septal defect may be the only cardiac defect, or it may occur in association with multiple cardiac anomalies.

The ventricular septum originates from two sources: the interventricular groove of the folded tubular heart that gives rise to the muscular part of the septum and the endocardial cushions that extend to form the membranous portion of the septum. The upper membranous portion of the septum is the last area to close, typically by the seventh week of gestation, and it is here that most defects occur. Depending on the size of the opening and the pulmonary vascular resistance, the signs and symptoms of a ventricular septal defect may range from an asymptomatic murmur to congestive heart failure.

The physical size of the ventricular septal defect is a major, but not the only, determinant of left-to-right shunt. The pulmonary vascular resistance in relation to systemic vascular resistance also determines the shunt’s magnitude. In a small communicating defect (<5 cm²), the higher pressure in the LV drives the shunt to the left, and the size of the defect limits the magnitude of the shunt. Most children with such defects are asymptomatic and have a low risk for development of pulmonary vascular disease.

In a larger, nonrestrictive shunt (usually >1 cm²), right and left ventricular pressure is equalized, and the degree of shunting is determined by the ratio of pulmonary to systemic vascular resistance. After birth in infants with large ventricular septal defects, pulmonary vascular resistance may remain higher than normal, and the size of the left-to-right shunt may initially be limited. As the pulmonary vascular resistance continues to fall in the first few weeks after birth because of normal involution of the media of the small pulmonary arterioles, the magnitude of the left-to-right shunt increases. Eventually, a large left-to-right shunt develops, and clinical symptoms (e.g., tachypnea, diaphoresis, especially with feeding, and failure to thrive) become apparent. In most cases during infancy,
pulmonary vascular pressure is only slightly elevated, and the major contributor to pulmonary hypertension is an increase in pulmonary blood flow. In some infants with a large septal defect, pulmonary arteriolar thickness never decreases. With continued exposure to high pulmonary blood flow, pulmonary vascular obstructive disease develops. In untreated patients, the pulmonary vascular resistance can eventually exceed the systemic resistance. In this case, a reversal of shunt flow occurs and the child demonstrates progressive cyanosis as deoxygenated blood moves from the right to the left side of the heart. These symptoms, coupled with irreversible changes in the pulmonary vasculature, represent an end-stage form of congenital heart disease called Eisenmenger complex. People who develop this have a life expectancy of about 43 years, and the cause of death is progressive heart failure.68

The treatment of a ventricular septal defect depends on the size of the defect, accompanying hemodynamic derangements, and symptomatology. Children with small or medium-sized defects may be followed without intervention if they remain free from signs of congestive heart failure or pulmonary hypertension. Ventricular defects do not increase in size, and some spontaneously close over time.52 Detailed 2-D echocardiography is usually adequate to diagnosis the size and position of a defect as well as to estimate pulmonary pressures. Cardiac catheterization is usually reserved for cases where it is necessary to confirm the degree and reversibility of pulmonary vascular resistance.

Congestive heart failure is treated medically. Symptomatic infants may require feeding supplements or tube feeding to promote growth and development. In the symptomatic infant in whom complete repair cannot be achieved because of size or other complicating lesions, a palliative procedure may be performed to reduce symptoms. Placement of a synthetic band around the main pulmonary artery (pulmonary artery banding) can reduce pulmonary blood flow until complete repair can be accomplished. Surgical closure of the defect is completed by placement of a synthetic or autologous patch effectively to close the shunt across the ventricular septum. These procedures are typically done electively in the infant or young child and are associated with low morbidity and mortality rates. Transcatheter device closure of ventricular septal defects remains an area of interest; however, difficulty with successful positioning of the devices has limited its applicability.

**Endocardial Cushion Defects.** The AV canal connects the atria to the ventricles during early cardiac development. The endocardial cushions surround this canal and contribute tissue to the lower part of the atrial septum, the upper part of the ventricular septum, the septal leaflet of the tricuspid valve, and the anterior leaflet of the mitral valve.73 Any flaw in the development of these tissues results in an endocardial cushion defect. Approximately 3% of all congenital heart defects are endocardial cushion defects, with a nearly equal incidence in boys and girls. Endocardial cushion defects have a strong association with Down syndrome and are seen in as much as 50% of children with Down syndrome.68

Several variations of endocardial cushion defects are possible. The defect may be described as partial or complete. The anatomy of the AV valve determines the classification. In partial AV canal defects, the two AV valve rings are complete and separate. The most common type of partial AV canal defect is an ostium primum defect, often associated with a cleft in the mitral valve. In a complete canal defect, there is a common AV valve orifice along with defects in both the atrial and ventricular septal tissue (see Fig. 32.25E). Other cardiac defects may be associated with endocardial cushion defects and most commonly include cardiac malposition defects and tetralogy of Fallot.74

Physiologically, endocardial cushion defects result in abnormalities similar to those described for atrial or ventricular septal defects. The direction and magnitude of a shunt in a child with an endocardial cushion defect are determined by the combination of defects and the child’s pulmonary and systemic vascular resistance. The hemodynamic effects of an isolated ostium primum defect are those of the previously described atrial septal defect. These children are largely asymptomatic during childhood. With a complete AV canal defect, pulmonary blood flow is increased after pulmonary vascular resistance falls because of left-to-right shunting across both the ventricular and atrial septal defects. Children with complete defects often have effort intolerance, easy fatigability, failure to thrive, recurrent infections, and other signs of congestive heart failure, particularly when the shunt is large. Pulmonary hypertension and increased pulmonary vascular resistance result if the lesion is left untreated.

The timing of treatment for endocardial cushion defects is determined by the severity of the defect and symptoms. With an ostium primum defect, surgical repair usually is planned on an elective basis before the child reaches school age. The defect in the atrial septum is closed with a patch, and mitral valvuloplasty is performed if the valve is regurgitant. Corrective surgery is required for all complete AV canal defects. This is typically performed early in the infant’s life and requires patching of both the atrial and ventricular septal defects and separation of the AV valve apparatus to create competent mitral and tricuspid valves. Infants with severe symptoms may require a palliative procedure where the main pulmonary artery is banded to reduce pulmonary blood flow. This typically improves the infant’s ability to grow and develop until a complete repair can be performed. Total surgical repair of complete AV canal defects can be accomplished with low operative risk. Reoperation may be required in approximately 11.7% of children.

**Pulmonary Stenosis.** Obstruction of blood flow from the right ventricle to the pulmonary circulation is termed pulmonary stenosis. The obstruction can occur as an isolated valvular lesion, within the right ventricular chamber, in the pulmonary arteries, or as a combination of stenoses in multiple areas. It is a relatively common defect, estimated to account for approximately 10% of all congenital cardiac disease, and is often associated with other abnormalities.72
Pulmonary valvular defects, the most common type of obstruction, usually produce some impairment of pulmonary blood flow and increase the workload imposed on the right side of the heart (see Fig. 32.25D). Most children with pulmonic valve stenosis have mild stenosis that does not increase in severity. These children are largely asymptomatic and are diagnosed by the presence of a systolic murmur. Moderate or greater stenosis has been shown to progress over time, particularly before 12 years of age, so these children require careful follow-up. Critical pulmonary stenosis in the neonate is evidenced by cyanosis due to right-to-left atrial-level shunting and right ventricular hypertension. These infants require prostaglandin $E_2$ to maintain circulation to the lungs through the ductus arteriosus.\(^72\)

Pulmonary valvotomy is the treatment of choice for all valvular defects with pressure gradients from the right ventricle to the pulmonary circulation greater than 30 mm Hg. Transcatheter balloon valvuloplasty has been quite successful in this lesion. Stenosis in the peripheral pulmonary arteries can also be effectively treated with balloon angioplasty.\(^72\)

Recently, stents have been used with success. Stents are used for children with pulmonary artery stenosis to keep the vessels open. This is used when balloon dilatation has failed.\(^68\)

**Tetralogy of Fallot.** Tetralogy of Fallot is the most common cyanotic congenital heart defect.\(^68\) As the name implies, tetralogy of Fallot consists of four associated defects:

1. A ventricular septal defect involving the membranous septum and the anterior portion of the muscular septum
2. Dextroposition or shifting to the right of the aorta, so that it overrides the right ventricle and is in communication with the septal defect
3. Obstruction or narrowing of the pulmonary outflow channel, including pulmonic valve stenosis, a decrease in the size of the pulmonary trunk, or both
4. Hypertrophy of the right ventricle because of the increased work required to pump blood through the obstructed pulmonary channels\(^75\) (see Fig. 32.25C)

Variations of the defect can be a right aortic arch and a persistent left superior vena cava. When this is seen it can be called *pentalogy of Fallot*.\(^68\)

Cyanosis is caused by a right-to-left shunt across the ventricular septal defect. The degree of cyanosis is determined by the restriction of blood flow into the pulmonary bed. Right ventricular outflow obstruction causes deoxygenated blood from the right ventricle to shunt across the ventricular septal defect and be ejected into the systemic circulation. The degree of obstruction may be dynamic and can increase during periods of stress, causing hypercyanotic attacks (“tet spells”). These spells typically occur in the morning during crying, feeding, or defecating. These activities increase the infant’s oxygen requirements. Crying and defecating may further increase pulmonary vascular resistance, thereby increasing right-to-left shunting and decreasing pulmonary blood flow. With the hypercyanotic spell, the infant becomes acutely cyanotic, hyperpneic, irritable, and diaphoretic. Later in the spell, the infant becomes limp and may lose consciousness. Placing the infant in the knee–chest position increases systemic vascular resistance, which increases pulmonary blood flow and decreases right-to-left shunting. During a hypercyanotic spell, toddlers and older children may spontaneously assume the squatting position, which functions like the knee–chest position to relieve the spell. Turbulent flow across the narrow right ventricular outflow track produces a characteristic harsh systolic ejection murmur. Auscultation during a hypercyanotic spell reveals a diminished or absent murmur due to the dramatic reduction in pulmonary blood flow.\(^75\)

Total surgical correction is required for all children with tetralogy of Fallot. However, before surgery, iron deficiency anemia should be addressed in order to prevent stroke. Dehydration is monitored closely to prevent thrombotic complications, propranolol can be administered to prevent hypoxic spells, and sodium bicarbonate and alpha-adrenergic agonists are administered if acidosis.

Early definitive repair in infancy is currently advocated in most centers experienced in intracardiac surgery in infants. When extreme cyanosis is present in a small infant or when there is associated marked hypoplasia of the pulmonary arteries, a palliative procedure to facilitate pulmonary blood flow may be necessary. This is accomplished by placing a prosthetic shunt between a systemic artery and the pulmonary artery (modified Blalock-Taussig shunt). Balloon dilation of the pulmonary valve may also afford palliation in some infants. Total correction is then carried out later in infancy or early childhood. Complete repair includes patch closure of the ventricular septal defect and relief of any right ventricular outflow tract obstruction. Repair is associated with a mortality rate of less than 3%; however, patients need long-term follow-up to monitor for residual lesions, right ventricular dilation or dysfunction, and arrhythmias.\(^75\) They also need to be monitored since they continue to be at risk for IE.

**Transposition of the Great Arteries.** In complete transposition of the great arteries, the aorta arises from the right ventricle, and the pulmonary artery arises from the LV (see Fig. 32.25F). Complete transposition occurs in 1 per 4000 live births and is the most common reason for pediatric cardiology referral in the first 2 weeks of life.

Cyanosis is the most common presenting symptom resulting from an anomaly that allows the systemic venous return to be circulated through the right heart and ejected into the aorta, and the pulmonary venous return to be recirculated to the lungs through the LV and main pulmonary artery.\(^68\) In infants born with this defect, survival depends on communication between the right and left sides of the heart in the form of a patent ductus arteriosus or septal defect. Ventricular septal defects are present in 50% of infants, of which 10% have a small VSD, with transposition of the great arteries at birth and may allow effective mixing of blood. Prostaglandin $E_2$ should be administered to neonates when this lesion is suspected in an effort to maintain the patency of the ductus arteriosus. Balloon atrial septostomy may be done to increase the blood
flow between the two sides of the heart. In this procedure, a balloon-tipped catheter is inserted into the heart through the vena cava and then passed through the foramen ovale into the left atrium. The balloon is then inflated and pulled back through the foramen ovale, enlarging the opening as it goes.

Corrective surgery is essential for long-term survival. An arterial switch procedure, the current operation of choice, has survival rates greater than 90%.68 This procedure, which corrects the relation of the systemic and pulmonary blood flows, is preferably performed in the first 2 to 3 weeks of life, before the postnatal reduction in pulmonary vascular resistance occurs. The coronary arteries are moved to the left-sided great artery, and any ventricular septal defects are closed during the same operation. Complications of the arterial switch procedure may include coronary insufficiency, supravalvar pulmonary stenosis, neoaortic regurgitation, and rhythm abnormalities.74

Coarctation of the Aorta. Coarctation of the aorta is a localized narrowing of the aorta, proximal to (preductal), distal to (postductal), or opposite the entry of the ductus arteriosus (juxtaductal; see Fig. 32.25H). Approximately 98% of coarctations are juxtaductal. Constriction of aberrant ductal tissue extending into the aortic wall is believed to be the cause of obstruction.72 The anomaly occurs more often in males than females, as much as 3:1. It is frequently associated with other congenital cardiac lesions, most commonly bicuspid aortic valve 46%, and occurs in approximately 10% of subjects with Turner syndrome, suggesting a genetic linkage.68,72

The classic sign of coarctation of the aorta is a disparity in pulsations and blood pressures in the arms and legs. The femoral, popliteal, and dorsalis pedis pulsations are weak or delayed compared with the bounding pulses of the arms and carotid vessels. Normally, the systolic blood pressure in the legs obtained by the cuff method is 10 to 20 mm Hg higher than in the arms. In coarctation, the pressure in the legs is lower and may be difficult to obtain. Patients with coarctation are often identified during a diagnostic workup for hypertension. Most patients with moderate coarctation remain otherwise asymptomatic owing to collateral vessels that form around the area of narrowing. Left untreated, however, coarctation will result in left ventricular hypertension and hypertrophy and significant systemic hypertension. Infants with severe coarctation demonstrate early symptoms of heart failure and may present in critical condition upon ductal closure. Reopening of the duct with prostaglandin E, if possible, and emergent surgery are needed in this subgroup.72

Children with coarctation causing a blood pressure gradient between the arms and legs of 20 mm Hg or greater should be treated ideally by 2 years of age to reduce the likelihood of persistent hypertension.72 A surgical approach typically involves resection of the narrowed segment of the aorta and end-to-end anastomosis of healthy tissue. This can usually be accomplished without cardiopulmonary bypass, with a mortality rate near zero. Balloon angioplasty with or without stent placement has also been used, although the presence of residual gradients and the reliability of the surgical approach have limited this technique.68,72 The most common complications after repair of coarctation are persistent hypertension and recoarctation. Operative mortality rates increase if an associated defect is present.

Functional Single-Ventricle Anatomy. Several forms of complex congenital heart disease result in only one functional ventricle. There may be a single right or a single LV, or a ventricle of indeterminate morphology. Functional single-ventricle anatomy is the most common form of congenital heart disease diagnosed during fetal life because of the inability to obtain a four-chamber cardiac view on routine prenatal ultrasonography. Hypoplastic left heart syndrome is the most common form of single right ventricular anatomy. Tricuspid valve atresia is the most common cause of a single LV. Several other forms of double-inlet ventricle have been described; however, all forms of this disease result in similar pathologic effects and follow a common pathway of intervention.68

All forms of single-ventricle anatomy result in a common mixing chamber of pulmonary and systemic venous return and cause varying degrees of cyanosis. The single ventricle must supply both the pulmonary and systemic circulations.68 The amount of blood flow to each circulation is determined by the resistance in each system. As pulmonary vascular resistance falls, flow to the pulmonary circulation will be preferential and systemic circulation will be compromised. In some defects, such as hypoplastic left heart syndrome, systemic flow depends on a patent ductus arteriosus. Neonates with this lesion typically present with extreme cyanosis and symptoms of heart failure as the duct begins to close.72

Although functional single-ventricle anatomy cannot be completely repaired, the surgical palliation of these defects has been one of the most innovative accomplishments in intervention for congenital heart disease. The goal of surgical palliation is to redirect systemic venous return directly to the pulmonary arteries and allow the single ventricle to deliver oxygenated blood to the systemic circulation. This is accomplished in a series of two to three staged surgical interventions during the child’s first years of life. Currently a modified Fontan and Baudet approach is done surgically. The goal is to bypass the right side of the heart, so blood flow to systemic venous blood goes directly to the pulmonary arteries; this allows the single-ventricle chamber to pump into the systemic circulation. Cardiac transplantation is also used as an intervention for the most complex forms of single-ventricle congenital heart disease (Fig. 32.26).

Survival rates for children with complex forms of single-ventricle heart disease have improved markedly, but long-term outcomes remain uncertain. Ventricular dysfunction, arrhythmias, and thromboses plague this population of patients. Defining the optimal medical and surgical management strategies for these patients remains an active area of research in pediatric cardiology and cardiac surgery.68,76

Adults with Congenital Heart Disease

Successful treatment of congenital heart disease in the pediatric population has resulted in a growing number of adult survivors with a variety of repaired, un repaired, and palliated
congenital cardiac lesions. An epidemiologic study on the prevalence and age distribution of congenital heart disease identified a prevalence of 6 per 1000 adults.77,78

Although the majority of adults with congenital heart disease will have undergone treatment and perhaps surgery as children, most congenital heart defects must be considered chronic conditions requiring long-term surveillance and care. Only the simplest lesions, such as patent ductus arteriosus and uncomplicated secundum atrial septal defect, can be considered completely repaired.79 Chronic physiologic concerns include arrhythmias, hemodynamic problems, complications of prolonged cyanosis, endocarditis, residual lesions, and the need for reoperation. The underlying heart defect can also have significant implications for other aspects of health, such as exercise tolerance, noncardiac surgery, and pregnancy. Several important psychosocial issues also require consideration, including neurocognitive achievement, employment, insurability, family planning, treatment adherence, and understanding of the underlying condition and risks. Life expectancy for some of the most complex lesions (e.g., hypoplastic left heart syndrome) is unknown because the oldest survivors to date were born in the 1980s. A growing medical specialty has emerged designed specifically to provide adults with congenital heart defects the specialized services they need from practitioners who understand both the complexities of their cardiac problems and other issues of adult health care.

**Kawasaki Disease**

Kawasaki disease, also known as mucocutaneous lymph node syndrome, is an acute febrile disease of young children. First described in Japan in 1967 by Dr. Tomisaku Kawasaki, the disease affects the skin, brain, eyes, joints, liver, lymph nodes, and heart. The disease is the most common cause of acquired heart disease in young children, with 15% to 25% of cases resulting in coronary artery aneurysms or ectasias that may lead to myocardial infarction, sudden death, or chronic coronary insufficiency.80 More than 4000 children with Kawasaki disease are hospitalized annually in the United States.80 Over 80% of patients with Kawasaki disease are 4 years of age or younger, with a male-to-female ratio of 1.5:1. Although most common in Japan, the disease affects children of many races, occurs worldwide, and is increasing in frequency.

**Pathogenesis**

The disease is characterized by a vasculitis (i.e., inflammation of the blood vessels) that begins in the small vessels (i.e., arterioles, venules, and capillaries) and progresses to involve some of the larger arteries, such as the coronaries. The exact etiology and pathogenesis of the disease remain unknown, but it is thought to be of immunologic origin.54 Immunologic abnormalities, including increased activation of helper T cells and increased levels of immune mediators and antibodies that destroy endothelial cells, have been detected during the acute phase of the disease. It has been hypothesized that some unknown antigen, possibly a common infectious agent, triggers the immune response in a genetically predisposed child.

**Clinical Manifestations**

The clinical course of the disease has been described in three phases: the acute, subacute, and convalescent phases.54,80 The acute phase begins with an abrupt onset of fever, followed by conjunctivitis, rash, involvement of the oral mucosa, redness and swelling of the hands and feet, and enlarged cervical lymph nodes (Fig. 32.27). The fever typically is high, reaching 40°C (104°F) or more; has an erratic spiking pattern; is unresponsive to antibiotics; and persists for 5 or more days. The conjunctivitis, which is bilateral, begins shortly after the onset of fever, persists throughout the febrile course of the disease, and may last as long as 4 to 8 weeks. There is no exudate, discharge, or conjunctival ulceration, differentiating it from many other types of conjunctivitis. The rash usually is deeply erythematous and may take several forms, the most common of which is a nonpruritic urticarial rash with large erythematous plaques, or a measles-type rash. Although the rash usually is generalized, it may be accentuated centrally or peripherally. Some children have a perianal rash with a diaper-like distribution. Oropharyngeal manifestations include fissuring of the lips, diffuse erythema of the oropharynx, and hypertrophic papillae of the tongue, creating a “strawberry” appearance. The hands and feet become swollen and painful and have reddened palms and soles. The rash, oropharyngeal manifestations, and changes in hands and feet appear within 1 to 3 days of fever onset and usually disappear as the fever subsides. Lymph node involvement is the least constant feature of the disease. It is cervical and unilateral, with a single, firm, enlarged lymph node mass that usually is larger than 1.5 cm in diameter.

The subacute phase begins with defervescence and lasts until all signs of the disease have disappeared. During the
Diagnosis and Treatment

No specific diagnostic test for Kawasaki disease is available; therefore, the diagnosis is made on clinical grounds following published guidelines. The guidelines specify fever persisting at least 5 days or more without another source in association with at least four principal features, including oral changes that may include erythema or cracking of the lips, strawberry tongue, and erythema of the oral mucosa; bilateral, nonexudative conjunctivitis; polymorphous rash, generally truncal involvement, nonvesicular; changes of extremities that may include erythema and edema of the hands or feet and desquamation of fingers and toes 1 to 3 weeks after onset of illness; and cervical lymphadenopathy, often unilateral, with at least one node that is 1.5 cm in size. Chest radiographs, ECG tests, and 2-D echocardiography are used to detect coronary artery involvement and follow its progress. Coronary angiography may be used to determine the extent of coronary artery involvement.

Intravenous gamma globulin (2 g/kg single infusion) and aspirin are considered the best therapies for prevention of coronary artery abnormalities in children with Kawasaki disease. During the acute phase of the illness, aspirin usually is given in larger doses (80 to 100 mg/kg/day divided in four doses) for its anti-inflammatory and antipyretic effects. After the fever is controlled, the aspirin dose is lowered (3 to 5 mg/kg/day, single dose), and the drug is given for its anti-platelet-aggregating effects for up to 8 weeks.

Recommendations for cardiac follow-up evaluation (i.e., stress testing and sometimes coronary angiography) are based on the level of coronary artery changes. Anticoagulant therapy may be recommended for children with multiple or large coronary aneurysms. Some restrictions in activities...
such as competitive sports may be advised for children with significant coronary artery abnormalities.54,80

**IN SUMMARY**

Congenital heart defects arise during fetal heart development, which occurs during weeks 3 through 8 after conception, and reflect the stage of development at the time the causative event occurred. Several factors contribute to the development of congenital heart defects, including genetic and chromosomal influences, viruses, and environmental agents such as drugs and radiation. The exact cause of the defect often is unknown. These defects are relatively common and are the most common cause of death related to a birth defect.

Congenital heart defects may produce no effects, or they may markedly affect cardiac function. The defects may produce shunting of blood from the right to the left side of the heart or from the left to the right side of the heart. Left-to-right shunts typically increase the volume of the right side of the heart and pulmonary circulation, and right-to-left shunts transfer deoxygenated blood from the right side of the heart to the left side, diluting the oxygen content of blood that is being ejected into the systemic circulation and causing cyanosis. The direction and degree of shunt depend on the size and position of the defect that connects the two sides of the heart and the difference in resistance between the two sides of the circulation. Congenital heart defects often are classified as defects that produce cyanosis and those that produce little or no cyanosis. Depending on the severity of the defect, congenital heart defects may be treated medically or surgically. Medical and surgical treatment often is indicated in children with severe defects.

Kawasaki disease is an acute febrile disease of young children that affects the skin, brain, eyes, joints, liver, lymph nodes, and heart. The disease can produce aneurysmal disease of the coronary arteries and is the most common cause of acquired heart disease in young children.

Heart muscle is unique in that it is capable of generating and rapidly conducting its own electrical impulses or action potentials. These action potentials result in excitation of muscle fibers throughout the myocardium. Impulse formation and conduction result in weak electrical currents that spread through the entire body. It is these impulses that are recorded on an electrocardiogram. Disorders of cardiac impulse generation and conduction range from benign arrhythmias to those causing serious disruption of heart function and sudden cardiac death.

In certain areas of the heart, the myocardial cells have been modified to form the specialized cells of the conduction system. These specialized cells have the ability to self-excitation, which is the capability of initiating and conducting impulses. It is the conduction system that maintains the pumping efficiency of the heart. Specialized pacemaker cells generate impulses at a faster rate than other types of heart tissue, and the conduction tissue transmits these impulses more rapidly than other cardiac cell types. Because of these properties, a normal conduction system controls the rhythm of the heart.

The specialized excitatory and conduction system of the heart consists of the sinoatrial (SA) node, in which the normal
The A V junction connects the two conduction systems and provides for one-way conduction between the atria and ventricles. The AV node is a compact, ovoid structure measuring approximately 1 × 3 × 5 mm and located on the posterior wall slightly beneath the right atrial endocardium, anterior to the opening of the coronary sinus, and immediately above the insertion of the septal leaflet of the tricuspid valve. It is important to note that everywhere except for the AV node in a healthy heart, the atrial muscle is separated from the ventricular muscle in order to prevent cardiac impulses firing inappropriately.

The AV node is divided into three functional regions:

- The AN or transitional region, located between the atria and the rest of the node
- The N or middle region (i.e., the node proper)
- The NH region, in which nodal fibers merge with the bundle of His, which is the upper portion of the specialized conduction system

In the AN portion of the node, atrial fibers connect with very small junctional fibers of the node itself. The velocity of conduction through the AN and N fibers is very slow (approximately one half that of normal cardiac muscle), which greatly delays transmission of the impulse. A further delay occurs as the impulse travels through the N region into the NH region, which connects with the bundle of His, which is the upper portion of the specialized conduction system.

In the AN portion of the node, atrial fibers connect with very small junctional fibers of the node itself. The velocity of conduction through the AN and N fibers is very slow (approximately one half that of normal cardiac muscle), which greatly delays transmission of the impulse. A further delay occurs as the impulse travels through the N region into the NH region, which connects with the bundle of His, which is the upper portion of the specialized conduction system.

The atria and ventricles would beat independently of each other if the transmission of impulses through the AV node were blocked.

The Purkinje system, which initiates ventricular conduction, has large fibers that allow for rapid conduction.
the impulse enters the Purkinje system, it spreads almost immediately to the whole ventricle (0.03 second). This rapid rate of conduction throughout the Purkinje system is necessary for the swift and efficient ejection of blood from the heart. The fibers of the Purkinje system originate in the AV node and proceed to form the bundle of His, which extends through the fibrous tissue between the valves of the heart and into the ventricular system. Because of its proximity to the aortic valve and the mitral valve ring, the bundle of His is predisposed to inflammation and deposits of calcified debris that can interfere with impulse conduction.\(^1\) The bundle of His penetrates into the ventricles and almost immediately divides into right and left bundle branches that straddle the interventricular septum. Branches from the anterior and posterior descending coronary arteries provide the blood supply for the His bundle, making this conduction site less susceptible to ischemic damage, unless the damage is extensive.\(^2\) The bundle of His divides further into two segments: the left posterior and anterior fascicles. These Purkinje fibers transmit the impulse almost simultaneously to the right and left ventricular endocardium in a healthy conduction system.

The AV nodal fibers, when not stimulated, discharge at an intrinsic rate of 40 to 60 times a minute, and the Purkinje fibers discharge 15 to 40 times per minute. Although the AV node and Purkinje system have the ability to control the rhythm of the heart, they do not normally do so because the discharge rate of the SA node is considerably faster. Each time the SA node discharges, its impulses are conducted into the AV node and Purkinje fibers, causing them to fire. The AV node can assume the pacemaker function of the heart, should the SA node fail to discharge, and the Purkinje system can assume the pacemaker function of the ventricles should the AV node fail to conduct impulses from the atria to the ventricles. Under these circumstances, the heart rate reflects the intrinsic firing rate of the prevailing structures.

### Action Potentials

An action potential represents the sequential change in electrical potential that occurs across a cell membrane when excitation occurs and causes the heart to conduct the atrium and ventricle. These potential or voltage differences, often referred to as membrane potentials, represent the flow of current associated with the passage of ions through ion channels in the cell membrane. The sodium (Na\(^+\)), potassium (K\(^+\)), and calcium (Ca\(^{2+}\)) ions are the major charge carriers in cardiac muscle cells. Disorders of the ion channels along with disruption in the flow of these current-carrying ions are increasingly being linked to the generation of cardiac arrhythmias and conduction disorders.

Action potentials can be divided into three phases:

1. **Resting or unexcited state**
2. **Depolarization**
3. **Repolarization**

During the resting phase, cardiac cells exhibit a resting membrane potential that typically ranges from ~60 to ~90 mV. The negative sign before the voltage indicates that the inside of the membrane is negatively charged in relation to the outside (Fig. 33.2A). Although different kinds of ions are found both inside and outside of the membrane, the membrane potential is determined largely by Na\(^+\) and K\(^+\) and the membrane permeability for these two ions. During the resting phase of the membrane potential, the membrane is selectively permeable to K\(^+\) and nearly impermeable to Na\(^+\). As a result, K\(^+\) diffuses out of the cell along its concentration gradient, causing a relative loss of positive ions from inside the membrane. The result is an uneven distribution of charge with negativity on the inside and positivity on the outside.

**Depolarization** represents the period of time (measured in milliseconds [ms]) during which the polarity of the membrane potential is reversed. It occurs when the cell membrane suddenly becomes selectively permeable to a current-carrying ion such as Na\(^+\), allowing it move into a cell and change the membrane potential so it becomes positive on the inside and negative on the outside (Fig. 33.2B).

---

**KEY POINTS**

**CARDIAC CONDUCTION SYSTEM**

- Normally, impulses are generated in the SA node, which has the fastest rate of firing, and travel through the AV node to the Purkinje system in the ventricles.
- Cardiac action potentials are divided into five phases: phase 0, or the rapid upstroke of the action potential; phase 1, or early repolarization; phase 2, or the plateau; phase 3, or final repolarization period; and phase 4, or diastolic repolarization period.

**FIGURE 33.2** The flow of charge during impulse generation in excitable tissue. During the resting state (A), opposite charges are separated by the cell membrane. Depolarization (B) represents the flow of charge across the membrane, and repolarization (C) denotes the return of the membrane potential to its resting state.
Repolarization involves reestablishment of the resting membrane potential. It is a complex and somewhat slower process, involving the outward flow of electrical charges and the return of the membrane potential to its resting state. During repolarization, membrane permeability for K+ again increases, allowing the positively charged K+ to move out across the membrane. This outward movement removes positive charges from inside the cell; thus, the voltage across the membrane again becomes negative on the inside and positive on the outside (Fig. 33.2C). The adenosine triphosphatase (ATPase)-dependent sodium–potassium pump assists in repolarization by pumping positively charged Na+ out across the cell membrane and returning K+ to the inside of the membrane.

**Action Potential Phases**

The action potentials in cardiac muscle are typically divided into five phases:

1. **Phase 0**—upstroke or rapid depolarization
2. **Phase 1**—early repolarization period
3. **Phase 2**—plateau
4. **Phase 3**—final, rapid repolarization period
5. **Phase 4**—diastolic depolarization (Fig. 33.3B)

Cardiac muscle has three types of membrane ion channels that contribute to the voltage changes that occur during the different phases of the cardiac action potential. They are the fast Na+ channels, slow calcium (Ca++) channels, and K+ channels.

During **phase 0**, in atrial and ventricular muscle and in the Purkinje system, the fast Na+ channels in the cell membrane are stimulated to open, resulting in the rapid influx of Na+. The point at which the Na+ channels open is called the *depolarization threshold.* When the cell has reached this threshold, a rapid influx of Na+ occurs. The exterior of the cell now is negatively charged in relation to the highly positive interior of the cell. This influx of Na+ produces a rapid, positively directed change in the membrane potential, resulting in the electrical spike and overshoot during phase 0 of the action potential. The membrane potential shifts from a resting membrane potential of approximately −90 to +20 mV. The rapid depolarization that comprises phase 0 is responsible for the QRS complex on the electrocardiogram (ECG) (Fig. 33.3A). Depolarization of a cardiac cell tends to cause adjacent cells to depolarize because the voltage spike of the cell’s depolarization stimulates the Na+ channels in nearby cells to open. Therefore, when a cardiac cell is stimulated to depolarize, a wave of depolarization is propagated across the heart, cell by cell.

**Phase 1** occurs at the peak of the action potential and signifies inactivation of the fast Na+ channels with an abrupt decrease in sodium permeability. The slight downward slope is thought to be caused by the influx of a small amount of negatively charged chloride ions and efflux of potassium. The decrease in intracellular positivity reduces the membrane potential to a level near 0 mV, from which the plateau, or phase 2, arises.

**Phase 2** represents the plateau of the action potential. If K+ permeability increased to its resting level at this time, as it does in nerve fibers or skeletal muscle, the cell would repolarize rapidly. Instead, K+ permeability is low, allowing the membrane to remain depolarized throughout the phase 2 plateau. A concomitant influx of Ca++ into the cell through the slow Ca++ channels contributes to the phase 2 plateau. Calcium ions entering the muscle during this phase also play a key role in the contractile process. These unique features of the phase 2 plateau cause the action potential of cardiac muscle (several hundred milliseconds) to last 3 to 15 times longer than that of skeletal muscle and produce a corresponding increased period of contraction. The phase 2 plateau coincides with the ST segment of the ECG.

**Phase 3** reflects rapid repolarization and begins with the downslope of the action potential. During the phase 3 repolarization period, the slow Ca++ channels close and the influx of Ca++ and Na+ ceases. There is a sharp rise in K+ permeability, contributing to the rapid outward movement of K+ and reestablishment of the resting membrane potential (−90 mV). At the conclusion of phase 3, the distribution of K+ and Na+ returns the membrane to the normal resting state. The T wave on the ECG corresponds with phase 3 of the action potential.

**Phase 4** represents the resting membrane potential. During phase 4, the activity of the Na+/K+-ATPase pump contributes to maintaining the resting membrane potential by transporting Na+ out of the cell and moving K+ back in. Phase 4 corresponds to diastole.
Fast and Slow Responses

There are two main types of action potentials in the heart—the fast response and the slow response. The fast response occurs in the normal myocardial cells of the atria, the ventricles, and the Purkinje fibers (Fig. 33.4A). It is characterized by the opening of voltage-dependent Na⁺ channels called the fast sodium channels. The fast-response cardiac cells do not normally initiate cardiac action potentials. The fast-response cells have a constant resting potential, rapid depolarization, and then a longer period of sustained depolarization before repolarization. This allows impulse conduction to be rapid to adjacent cells. Myocardial fibers with a fast response are capable of conducting electrical activity at relatively rapid rates (0.5 to 5.0 m/second), thereby providing a high safety factor for conduction.

The slow response occurs in the SA node, which is the natural pacemaker of the heart, and the conduction fibers of the AV node (Fig. 33.4B). The hallmark of these pacemaker cells is a spontaneous phase 4 depolarization. The membrane permeability of these cells allows a slow inward leak of current to occur through the slow channels during phase 4. This leak continues until the threshold for firing is reached, at which point the cell spontaneously depolarizes. Under normal conditions, the slow response, sometimes referred to as the calcium current, does not contribute significantly to depolarization of the atria and ventricles. Its primary role in normal atrial and ventricular cells is to provide for the entrance of calcium for the excitation-contraction mechanism that couples the electrical activity with muscle contraction.

The rate of pacemaker cell discharge varies with the resting membrane potential and the slope of phase 4 depolarization (Fig. 33.3). Catecholamines (i.e., epinephrine and norepinephrine) increase heart rate by increasing the slope or rate of phase 4 depolarization. Acetylcholine, a parasympathetic mediator, slows the heart rate by decreasing the slope of phase 4.

The fast response of atrial and ventricular muscle can be converted to a slow pacemaker response under certain conditions. For example, such conversions may occur spontaneously in individuals with severe coronary artery disease and in areas of the heart where blood supply has been markedly compromised. Impulses generated by these cells can lead to ectopic beats and serious arrhythmias.

Absolute and Relative Refractory Periods

The pumping action of the heart requires alternating contraction and relaxation. There is a period in the action potential during which the membrane cannot be stimulated to generate another action potential (Fig. 33.5). This period, known as the absolute or effective refractory period, includes phases 0, 1, and 2 and part of phase 3. During this time, the cell cannot depolarize again under any circumstances. This acts as a safety margin for
The deflection points of an ECG are designated by the letters P, Q, R, S, and T. The P wave represents the SA node and atrial depolarization; the QRS complex (i.e., beginning of the Q wave to the end of the S wave) depicts ventricular depolarization; and the T wave portrays ventricular repolarization. The isoelectric line between the P wave and the Q wave represents depolarization of the AV node, bundle branches, and Purkinje system. Atrial repolarization occurs during ventricular depolarization and is hidden in the QRS complex. Figure 33.6 depicts the electrical activity of the conduction system on an ECG tracing.

The ECG records the potential difference in charge between two electrodes as the depolarization and repolarization waves move through the heart and are conducted to the skin surface. The shape of the recorder tracing is determined by the direction in which the impulse spreads through the heart muscle in relation to electrode placement. A depolarization wave that moves toward the recording electrode registers as a positive, or upward, deflection. Conversely, if the impulse moves away from the recording electrode, the deflection is downward, or negative. When there is no flow of charge between electrodes, the potential is zero, and a straight line is recorded at the baseline of the chart.

Conventionally, 12 leads (6 limb leads and 6 chest leads) are recorded for a diagnostic ECG, each providing a unique view of the electrical forces of the heart from a different position on the body’s surface. The six limb leads view the electrical forces as they pass through the heart on the frontal or vertical plane. The electrodes are attached to the four extremities or representative areas on the body near the shoulders and lower chest or abdomen. The electrical potential recorded in skeletal muscle, the refractory period is very short compared with the duration of contraction such that a second contraction cannot be initiated before the first is over, resulting in a summated tetanized contraction. In cardiac muscle, the absolute refractory period is almost as long as the contraction itself, ensuring that a second contraction cannot be stimulated until the first one is complete. The longer length of the absolute refractory period of cardiac muscle is important in maintaining the alternating contraction and relaxation that is essential to the pumping action of the heart and for the prevention of fatal arrhythmias.

Electrocardiography

The ECG is a graphic recording of the electrical activity of the heart or a picture of the heart as it contracts. The electrical currents generated by the heart spread through the body to the skin, where they can be sensed by appropriately placed electrodes, amplified, and viewed on an oscilloscope or chart recorder.

![Diagram of the ECG (lead II) and representative depolarization and repolarization of the atria and ventricles. The P wave represents atrial depolarization, the QRS complex ventricular depolarization, and the T wave ventricular repolarization. Atrial repolarization occurs during ventricular depolarization and is hidden under the QRS complex.](image-url)

from any one extremity should be the same no matter where the electrode is placed on the extremity. The six chest leads provide a view of the electrical forces as they pass through the heart on the horizontal plane. They are moved to different positions on the chest, including the right and left sternal borders and the left anterior surface (Fig. 33.7). The right lower extremity lead is used as a ground electrode.3 When indicated, additional electrodes may be applied to other areas of the body, such as the back or right anterior chest.

Although accurate ECG placement and lead selection are important aspects of ECG monitoring, there have been many studies that identified two common errors: inaccurate electrode placement and inappropriate lead selection for individual clinical situations.5 Improper lead placement can significantly change QRS morphology, resulting in misdiagnosis of cardiac arrhythmias or failure to detect existing conduction defects. It can also lead to people receiving improper potentially harmful treatments.

In persons with acute coronary syndromes (ACS), including unstable angina and ST-segment elevation and non-ST-segment elevation myocardial infarction (MI), careful cardiac ECG monitoring is imperative.10 People with ACS are at risk for development of extension of an infarcted area, ongoing myocardial ischemia, and life-threatening arrhythmias. Research has shown that ECG monitoring is more sensitive than a person’s report of symptoms for identifying transient ongoing myocardial ischemia. ECG monitoring also provides for more accurate and timely detection of ischemic events that predict early complications. Also, accurate ECG monitoring is essential for treatment options such as reperfusion strategies.11 It is recommended that all 12 ECG leads be used for monitoring patients with ACS because ischemic changes that occur may be evident in different leads at different times.12

The American Heart Association recently published practice standards for ECG monitoring in hospital settings.13 This rating system includes three categories:

- Class I—cardiac monitoring is necessary in most, if not all, people in this group.
- Class II—cardiac monitoring may be beneficial in some people, but it is not an essential component of care for these people.
- Class III—cardiac monitoring is not indicated because the risk of a serious event for these people is so low that monitoring is not viewed as therapeutic.

Examples of people categorized as class I are those who have been resuscitated from a cardiac arrest, are in the early phase of ACS, have unstable coronary syndromes or newly diagnosed high-risk coronary lesions, or have undergone cardiac surgery within the past 48 to 72 hours. In addition, recommendations for staffing, training, documentation, and approaches for improving quality of ECG monitoring were presented. It is recommended that these practice standards be adhered to when making determinations about ECG monitoring.

**IN SUMMARY**

The rhythmic contraction and relaxation of the heart rely on the specialized cells of the heart’s conduction system. Specialized cells in the SA node have the fastest inherent rate of impulse generation and act as the pacemaker of the heart. Impulses from the SA node travel through the atria to the AV node and then to the AV bundle and the ventricular Purkinje system. The AV node provides the only connection between the atrial and ventricular conduction systems. The atria and the ventricles function independently of each other when AV node conduction is blocked.

Action potentials represent the sequential changes in electrical potentials that are associated with the movement of current-carrying ions through ion channels in the cell membrane. The action potentials of cardiac muscle are divided into five phases: phase 0 represents depolarization and is characterized by the rapid upstroke of the action potential; phase 1 is characterized by a brief period of repolarization; phase 2 consists of a plateau, which prolongs the duration of the action potential; phase 3 represents repolarization; and phase 4 is the resting membrane potential. After an action potential, there is a refractory period during which the membrane is resistant to a second stimulus. During the absolute refractory period, the membrane is insensitive to stimulation. This period is followed by the relative
refractory period, during which a more intense stimulus is needed to initiate an action potential. The relative refractory period is followed by a supernormal excitatory period, during which a weak stimulus can evoke a response.

The ECG provides a means for monitoring the electrical activity of the heart. Conventionally, 12 leads (6 limb leads and 6 chest leads) are recorded for a diagnostic ECG, each providing a unique view of the electrical forces of the heart from a different position on the body’s surface. This procedure allows for advanced arrhythmia detection and early identification of ischemia- and infarction-related changes in people with ACS.

**Mechanisms of Arrhythmias and Conduction Disorders**

The specialized cells in the conduction system manifest four inherent properties that contribute to the genesis of all cardiac rhythms, both normal and abnormal. They are automaticity, excitability, conductivity, and refractoriness. An alteration in any of these four properties may produce arrhythmias or conduction defects.

The ability of certain cells in the conduction system spontaneously to initiate an impulse or action potential is referred to as automaticity. The SA node has an inherent discharge rate of 60 to 100 times/minute. It normally acts as the pacemaker of the heart because it reaches the threshold for excitation before other parts of the conduction system have recovered sufficiently to be depolarized. If the SA node fires more slowly or SA node conduction is blocked, another site that is capable of automaticity takes over as pacemaker.1,3 Other regions that are capable of automaticity include the atrial fibers that have plateau-type action potentials, the AV node, the bundle of His, and the bundle branch Purkinje fibers. These pacemakers have a slower rate of discharge than the SA node. The AV node has an inherent firing rate of 40 to 60 times/minute, and the Purkinje system fires at a rate of 15 to 40 times/minute. The SA node may be functioning properly, but because of additional precipitating factors, other cardiac cells can assume accelerated properties of automaticity and begin to initiate impulses. These additional factors might include injury, hypoxia, electrolyte disturbances, enlargement or hypertrophy of the atria or ventricles, and exposure to certain chemicals or drugs.

An *ectopic pacemaker* is an excitable focus outside the normally functioning SA node. These pacemakers can reside in other parts of the conduction system or in muscle cells of the atria or ventricles. A premature contraction occurs when an ectopic pacemaker initiates a beat. Premature contractions do not follow the normal conduction pathways, they are not coupled with normal mechanical events, and they often render the heart refractory or incapable of responding to the next normal impulse arising in the SA node. They occur without incident in persons with healthy hearts in response to sympathetic nervous system stimulation or other stimuli, such as caffeine. In the diseased heart, premature contractions may lead to more serious arrhythmias.

**Excitability** describes the ability of a cell to respond to an impulse and generate an action potential. Myocardial cells that have been injured or replaced by scar tissue do not possess normal excitability. For example, during the acute phase of an ischemic event, involved cells become depolarized. These ischemic cells remain electrically coupled to the adjacent nonischemic area; current from the ischemic zone can induce reexcitation of cells in the nonischemic zone.

**Conductivity** is the ability to conduct impulses, and **refractoriness** refers to the extent to which the cell is able to respond to an incoming stimulus. The refractory period of cardiac muscle is the interval in the repolarization period during...
which an excitable cell has not recovered sufficiently to be reexcited. Disturbances in conductivity or refractoriness predispose to arrhythmias.

The phenomenon, known as reentry, is the cause of many tachyarrhythmias.\(^1\) Under normal conditions, an electrical impulse is conducted through the heart in an orderly, sequential manner. The electrical impulse then dies out and does not reenter adjacent tissue because that tissue has already been depolarized and is refractory to immediate stimulation. However, fibers that were not activated during the initial wave of depolarization can recover excitability before the initial impulse dies out, and they may serve as a link to reexcite areas of the heart that were just discharged and have recovered from the initial depolarization.\(^2\) This activity disrupts the normal conduction sequence. For reentry to occur, there must be areas of slow conduction and a unidirectional conduction block (Fig. 33.8). For previously depolarized areas to repolarize adequately to conduct an impulse again, slow conduction is necessary. Unidirectional block is necessary to provide a one-way route for the original impulse to reenter, thereby blocking other impulses entering from the opposite direction from extinguishing the reentrant circuit.\(^3\) Reentry requires a triggering stimulus such as an extrasystole to start the circuit. If sufficient time has elapsed for the refractory period in the reentered area to end, a self-perpetuating, circuitous movement can be initiated, and an arrhythmia will occur.\(^2\)

Reentry may occur anywhere in the conduction system. The functional components of a reentry circuit can be large and include an entire specialized conduction system, or the circuit can be microscopic. It can include myocardial tissue, AV nodal cells, junctional tissue, or the ventricles. Factors contributing to the development of a reentrant circuit include ischemia, infarction, and elevated serum potassium levels. Scar tissue interrupts the normally low-resistance paths between viable myocardial cells, slowing conduction, promoting asynchronous myocardial activation, and predisposing to unidirectional conduction block. There are several forms of reentry. The first is anatomic reentry. It involves an anatomic obstacle around which the circulating current must pass and results in an excitation wave that travels in a set pathway.\(^2\) Arrhythmias that arise as a result of anatomic reentry are paroxysmal supraventricular tachycardias, as seen in Wolff-Parkinson-White syndrome, AF, atrial flutter, AV nodal reentry, and some ventricular tachycardias. Functional reentry does not rely on an anatomic structure to circle, but instead depends on the local differences in conduction velocity and refactoriness among neighboring fibers that allow an impulse to circulate repeatedly around an area.\(^2,3,13\) Spiral reentry is the most common form of this type of reentry.\(^3,14\) It is initiated by a wave of current that does not propagate normally after meeting refractory tissue. The broken end of the wave curls, forms a vortex, and permanently rotates. This phenomenon suppresses normal pacemaker activity and can result in AF.\(^2,14\) Arrhythmias observed with functional reentry are likely to be polymorphic because of changing circuits.\(^2\) Reflection is sometimes considered another form of reentry that can occur in parallel pathways of myocardial tissue or the Purkinje network. With reflection, the cardiac impulse reaches an area of depressed conduction, triggers the surrounding tissue, and then returns in a retrograde direction through the severely depressed region. Reflection differs from true reentry in that the impulse travels along the same pathway in both directions and does not require a circuit.\(^2\)

**Types of Arrhythmias and Conduction Disorders**

**Sinus Node Arrhythmias**

In a healthy heart driven by sinus node discharge, the rate ranges between 60 and 100 beats/minute. On the ECG, a P wave may be observed to precede every QRS complex. Normal sinus rhythm has been considered the “normal” rhythm of a healthy heart. In normal sinus rhythm, a P wave precedes each QRS complex, and the R-R intervals remain relatively constant over time (Fig. 33.9). Alterations in the function of the SA node lead to changes in rate or rhythm of the heartbeat.

For example, respiratory sinus arrhythmia is a cardiac rhythm characterized by gradual lengthening and shortening of R-R intervals (see Fig. 33.9). This variation in cardiac cycles is related to intrathoracic pressure changes that occur with respiration and resultant alterations in autonomic control of the SA node. Inspiration causes acceleration of the heart rate, and expiration causes slowing and does not require any treatment. Respiratory sinus arrhythmia accounts for most heart rate variability in healthy individuals. Heart rate variability is the beat-to-beat variation of the cardiac signal and is considered to be an index of autonomic nervous system balance. Therefore, a

![Figure 33.8](image-url)
disposes to other arrhythmias. Causes of sinus arrest include disease of the SA node, digitalis toxicity, stroke, MI, acute myocarditis, excessive vagal tone, sleep apnea, quinidine, lidocaine, and hyperkalemia or hypokalemia.\textsuperscript{17,18}

**Sinus Exit Block.** Sinus exit block happens when the sinus node fails to depolarize the atria. There are three types of sinus exit blocks, type I, II, or complete exit block. In type I degree exit block, the P-P interval shortens before the pause. In type II sinus exit block looks like sinus arrest except for the interval of P-P. The P-P intervals during a sinus exit block are exact multiples of the sinus cycle. Complete sinus exit block is the complete absence of P waves and is difficult to diagnose since it is similar to sinus arrest. Sinus exit block is usually short in nature, and treatment is only needed if it is prolonged and patients are symptomatic.\textsuperscript{17,19}

**Sinus Tachycardia.** Sinus tachycardia refers to a rapid heart rate (>100 beats/minute) that has its origin in the SA node (see Fig. 33.9). A normal P wave and PR interval should precede each QRS complex. The mechanism of sinus tachycardia is enhanced automaticity related to sympathetic stimulation or withdrawal of vagal tone. Sinus tachycardia is a normal response during fever, blood loss, anxiety, pain, and exercise, and in situations that incite sympathetic stimulation. It may be associated with congestive heart failure, MI, and hyperthyroidism. Pharmacologic agents such as atropine, isoproterenol, epinephrine, and quinidine also can cause sinus tachycardia.

**Sick Sinus Syndrome.** Sick sinus syndrome (SSS) is a term that describes a number of forms of cardiac impulse formation and intra-atrial and AV conduction abnormalities.\textsuperscript{17,19–23} The syndrome most frequently is the result of total or subtotal destruction of the SA node, areas of nodal–atrial discontinuity, inflammatory or degenerative changes of the nerves and ganglia surrounding the node, or pathologic changes in the atrial wall.\textsuperscript{17} In addition, occlusion of the sinus node artery may be a significant contributing factor. SSS is most often idiopathic but can be seen in patients with coronary artery disease, fibrosis infective processes, certain drugs, and collagen vascular diseases.\textsuperscript{19,23} In children, the syndrome is most commonly associated with congenital heart defects, particularly after corrective cardiac surgery.\textsuperscript{17}

The arrhythmias associated with the sick sinus syndrome include spontaneous persistent sinus bradycardia that is not appropriate for the physiologic circumstances, prolonged sinus arrest or exit block, combinations of SA and AV node conduction disturbances, or alternating paroxysms of rapid regular or irregular atrial tachyarrhythmias and periods of slow atrial and ventricular rates (bradycardia–tachycardia syndrome).\textsuperscript{17,19,22} Most commonly, the term sick sinus syndrome is used to refer to the bradycardia–tachycardia syndrome. The bradycardia is caused by disease of the sinus node (or other intra-atrial conduction pathways), and the tachycardia is caused by paroxysmal atrial or junctional arrhythmias. Individuals with this syndrome often are asymptomatic.

---

**Figure 33.9** Electrocardiographic tracings of rhythms originating in the sinus node. (A) Normal sinus rhythm (60 to 100 beats/minute). (B) Sinus bradycardia (<60 beats/minute). (C) Sinus tachycardia (>100 beats/minute). (D) Respiratory sinus arrhythmia, characterized by gradual lengthening and shortening of R-R intervals.

---

decreased heart rate variability has been associated with altered health states, including MI, congestive heart failure, hypertension, stable angina, diabetes mellitus, and chronic obstructive pulmonary disease (COPD).\textsuperscript{16}

**Sinus Bradycardia.** Sinus bradycardia describes a slow (<60 beats/minute) heart rate (see Fig. 33.9). In sinus bradycardia, a P wave precedes each QRS. A normal P wave and PR interval (0.12 to 0.20 second) indicates that the impulse originated in the SA node rather than in another area of the conduction system that has a slower inherent rate. Vagal stimulation as well as some medications decreases the firing rate of the SA node and conduction through the AV node to cause a decrease in heart rate. This rhythm may be normal in trained athletes, who maintain a large stroke volume, and during sleep. In most cases sinus bradycardia is benign unless it is associated with hemodynamic decompensation. It may also be an indicator of poor prognosis when it occurs in conjunction with acute MI and after resuscitation from cardiac arrest.\textsuperscript{17}

**Sinus Pause or Arrest.** Sinus arrest refers to failure of the SA node to discharge and results in an irregular pulse. An escape rhythm develops as another pacemaker takes over. Sinus arrest may result in prolonged periods of asystole and often pre-
The most common manifestations of sick sinus syndrome are lightheadedness, dizziness, and syncope, and these symptoms are related to the bradyarrhythmias. When persons with sick sinus syndrome experience palpitations, they are generally the result of tachyarrhythmias and are suggestive of the presence of bradyarrhythmia–tachycardia syndrome.

Treatment depends on the rhythm problem and frequently involves the implantation of a permanent pacemaker. Pacing for the bradycardia, combined with drug therapy to treat the tachycardia, often is required in the bradycardia–tachycardia syndrome. Medications that affect SA node discharge must be used cautiously if no pacemaker is implanted.

**KEY POINTS**

**SUPRAVENTRICULAR AND VENTRICULAR ARRHYTHMIAS**

- Supraventricular arrhythmias represent disorders of atrial rhythm or conduction above the ventricles.
- Ventricular arrhythmias represent disorders of ventricular rhythm or conduction and can be life threatening.

**Arrhythmias of Atrial Origin**

Impulses from the SA node pass through the conductive pathways in the atria to the AV node. Arrhythmias of atrial origin include premature atrial contractions (PAC), multifocal and focal atrial tachycardia, atrial flutter, and AF (Fig. 33.10).

**Premature Atrial Contractions.** PACs are contractions that originate in the atrial conduction pathways or atrial muscle cells and occur before the next expected SA node impulse. This impulse to contract usually is transmitted to the ventricle and back to the SA node. The location of the ectopic focus determines the configuration of the P wave. In general, the closer the ectopic focus is to the SA node, the more the ectopic complex resembles a normal sinus complex. The retrograde transmission to the SA node often interrupts the timing of the next sinus beat, such that a pause occurs between the two normally conducted beats. In healthy individuals, PACs may be the result of stress, alcohol, tobacco, or caffeine. They also have been associated with MI, digitalis toxicity, low serum potassium or magnesium levels, and hypoxia.

**Multifocal and Focal Atrial Tachycardia.** Multifocal atrial tachycardia is the firing of the several ectopic foci in the atrium, causing at least three distinct P-wave morphologies, at a rate faster than 100 beats/minute. Since this rhythm is irregularly irregular, it can be misdiagnosed with AF. This is usually seen in older adults with COPD, hypoxia, and electrolyte disorders. The basis for correction of the rhythm is correction of the underlying cause.

Focal atrial tachycardia is a regular rate at approximately 100 to 250 beats/minute, which originates in the atrial muscle. It arises from a single site in the right or left atrium. It can be termed paroxysmal atrial tachycardia (PAT) because it starts and ends suddenly. Incessant AT that lasts for more than 12 hours can be more harmful due to the rapid ventricular rates associated with it. It is usually associated with caffeine, alcohol intake, mitral valve disease, rheumatic heart disease, acute MI, COPD, hypokalemia, and digitalis toxicity. It can be treated by identifying the underlying cause, the use of antiarrhythmics, or if those fail a radiofrequency catheter ablation of the ectopic focus causing the AT.

**Atrial Flutter.** Atrial flutter is a rapid atrial ectopic tachycardia, with a rate that ranges from 240 to 450 beats/minute. There are two types of atrial flutter. Typical atrial flutter (sometimes called type I) is the result of a reentry rhythm in the right atrium that can be entrained and interrupted with atrial pacing techniques. The atrial rate in typical type I flutter usually is in the vicinity of 300 beats/minute, but it can range from 240 to 340 beats/minute. Other forms of atrial flutter (i.e., the so-called atypical or type II flutters) are now recognized.
as distinct types and include atrial macro-reentry caused by surgical scars, idiopathic fibrosis in areas of the atrium, or other anatomic or functional barriers in the atria. Because the barriers that constrain these flutters are variable, the ECG pattern of the atypical flutters can vary. Often, the flutter wave changes morphologically during the same episode of flutter, indicating multiple circuits or nonfixed conduction barriers.\textsuperscript{17}

In typical atrial flutter, the ECG reveals a defined sawtooth pattern in leads AVF, V\textsubscript{1}, and V\textsubscript{V}. The ventricular response rate and regularity are variable and depend on the AV conduction sequence. When regular, the ventricular response rate usually is a defined fraction of the atrial rate (i.e., when conduction from the atria to the ventricles is 2:1, an atrial flutter rate of 300 would result in a ventricular response rate of 150 beats/minute). The QRS complex may be normal or abnormal, depending on the presence or absence of preexisting intraventricular conduction defects or aberrant ventricular conduction.

Atrial flutter rarely is seen in normal, healthy people. It may be seen in people of any age in the presence of underlying atrial abnormalities. Subgroups that are at particularly high risk for development of atrial flutter include children, adolescents, and young adults who have undergone corrective surgery for complex congenital heart diseases.\textsuperscript{20,25}

**Atrial Fibrillation.** Atrial fibrillation (AF) is characterized as rapid disorganized atrial activation and uncoordinated contraction by the atria.\textsuperscript{25} In most cases multiple, small reentrant circuits are constantly arising in the atria, colliding, being extinguished, and arising again. Fibrillation occurs when the atrial cells cannot repolarize in time for the next incoming stimulus. AF is characterized on the ECG by a grossly disorganized pattern of atrial electrical activity that is irregular with respect to rate and rhythm and the absence of discernible P waves. Atrial activity is depicted by fibrillatory (f) waves of varying amplitude, duration, and morphology. These f waves appear as random oscillation of the baseline. Because of the random conduction through the AV node, QRS complexes appear in an irregular pattern.

AF is classified into three categories—paroxysmal, persistent, and permanent.\textsuperscript{26} Paroxysmal AF self-terminates and lasts no longer than 7 days, while persistent lasts greater than 7 days and usually requires intervention such as a cardioversion. AF is classified as permanent when attempts to terminate are failed and the person remains in AF. During AF, the atrial rate typically ranges from 400 to 600 beats/minute, with many impulses blocked at the AV node. The ventricular response is completely irregular ranging from 80 to 180 beats/minute in the untreated state. Because of changes in stroke volumes resulting from varying periods of diastolic filling, not all ventricular beats produce a palpable pulse. The difference between the apical rate and the palpable peripheral pulses is called the pulse deficit. The pulse deficit increases when the ventricular rate is high.

AF can be seen in people without any apparent disease, or it may occur in people with coronary artery disease, mitral valve disease, ischemic heart disease, hypertension, MI, pericarditis, congestive heart failure, digitalis toxicity, and hyperthyroidism. Spontaneous conversion to sinus rhythm within 24 hours of AF is common, occurring in up to two thirds of people with the disorder.\textsuperscript{23} If the duration of AF exceeds 24 hours, the likelihood of conversion decreases, and after 1 week of persistent arrhythmia, spontaneous conversion is rare.\textsuperscript{25} AF is the most common chronic arrhythmia, with an incidence and prevalence that increase with age. The incidence of AF increases with age. For example, it occurs in less than 0.5% of the population aged less than 50 years and increases by 2% at ages 60 to 69 years old. The prevalence is also greater in men than in women.\textsuperscript{25}

The symptoms of chronic AF vary. Some people have minimal symptoms, and others have severe symptoms, particularly at the onset of the arrhythmia. The symptoms may range from palpitations to acute pulmonary edema. Fatigue and other nonspecific symptoms are common in the elderly. The condition predisposes individuals to thrombus formation in the atria, with subsequent risk of embolic stroke.

The treatment of AF depends on its cause, regency of onset, and persistence. It can be treated with antiarrhythmic medications to control rate or medically convert to sinus rhythm. Also, anticoagulant medications may be used to prevent embolic stroke depending on their risk for stroke.\textsuperscript{27} Cardioversion may be considered in some persons, particularly when pulmonary edema or unstable cardiac status is present. Because conversion to sinus rhythm is associated with increased risk of thromboembolism, anticoagulation therapy is usually administered for at least 3 weeks before cardioversion is attempted in persons in whom the duration of AF is unknown or exceeds 2 to 3 days.\textsuperscript{26} Transesophageal echocardiography can be used to detect atrial thrombus, and transesophageal echo-guided cardioversion provides a means of ensuring that atrial thrombi are not present when cardioversion is attempted. Anticoagulant medication usually is continued after cardioversion.

**Paroxysmal Supraventricular Tachycardia.** Paroxysmal supraventricular tachycardia refers to tachyarrhythmias that originate above the bifurcation of the bundle of His and have a sudden onset and termination. The heart rate may be 140 to 240 beats/minute and be perfectly regular despite exercise or change in position. Most people remain asymptomatic except for an awareness of the rapid heartbeat, but some may experience shortness of breath, especially if the episodes are prolonged. The most common mechanism for paroxysmal supraventricular tachycardia is reentry. It may be the result of AV nodal reentry, Wolff-Parkinson-White syndrome (caused by an accessory conduction pathway between the atria and ventricles), or intra-atrial or sinus node reentry.

**Junctional Arrhythmias**

The AV node can act as a pacemaker in the event the SA node fails to initiate an impulse. Junctional rhythms can be transient or permanent, and they usually have a rate of 40 to 60 beats/minute. Junctional fibers in the AV node or bundle of His also can serve as ectopic pacemakers, producing premature junctional complexes. Another rhythm originating in the junctional tissues is
nonparoxysmal junctional tachycardia. This rhythm usually is of gradual onset and termination. However, it may occur abruptly if the dominant pacemaker slows sufficiently. The rate associated with junctional tachycardia ranges from 70 to 130 beats/minute, but it may be faster.7 The P waves may precede, be buried in, or follow the QRS complexes, depending on the site of the originating impulses. The clinical significance of nonparoxysmal junctional tachycardia is the same as for atrial tachycardias. Catheter ablation therapy has been used successfully to treat some individuals with recurrent or intractable junctional tachycardia. Nonparoxysmal junctional tachycardia is observed most frequently in individuals with underlying heart disease, such as inferior wall MI or myocarditis, or after open heart surgery. It also may be present in persons with digitalis toxicity.

Disorders of Ventricular Conduction and Rhythm

The junctional fibers in the AV node join with the bundle of His, which divides to form the right and left bundle branches. The bundle branches continue to divide and form the Purkinje fibers, which supply the walls of the ventricles (see Fig. 33.1). As the cardiac impulse leaves the junctional fibers, it travels through the AV bundle. Next, the impulse moves down the right and left bundle branches that lie beneath the endocardium on either side of the septum. It then spreads out through the walls of the ventricles. Interruption of impulse conduction through the bundle branches is called bundle branch block. These blocks usually do not cause alterations in the rhythm of the heartbeat. Instead, a bundle branch block interrupts the normal progression of depolarization, causing the ventricles to depolarize one after the other because the impulses must travel through muscle tissue rather than through the specialized conduction tissue. This prolonged conduction causes the QRS complex to be wider than the normal 0.08 to 0.12 second. The left bundle branch bifurcates into the left anterior and posterior fascicles. An interruption of one of these fascicles is referred to as a hemiblock.

Long QT Syndrome and Torsade de Pointes

The long QT syndrome (LQTS) is characterized by a prolongation of the QT interval that may result in a characteristic type of polymorphic ventricular tachycardia called torsade de pointes and sudden cardiac death.17,19,28 Torsade de pointes (i.e., “twisting or rotating around a point”) is a specific type of ventricular tachycardia (Fig. 33.11). The term refers to the polarity of the QRS complex, which swings from positive to negative and vice versa. The QRS abnormality is characterized by large, bizarre, polymorphic QRS complexes that vary, often from beat to beat, in amplitude and direction, as well as in rotation of the complexes around the isoelectric line. The rate of tachycardia is 100 to 180, but it can be as fast as 200 to 300 per minute. The rhythm is highly unstable and may terminate in ventricular fibrillation or revert to sinus rhythm.

Various agents and conditions that reduce the magnitude of outward repolarizing potassium currents enhance the magnitude of the inward depolarizing sodium and calcium currents, or both can cause LQTS. Thus, there is delayed repolarization of the ventricles with development of early depolarizing afterpotentials that initiate the arrhythmia. Typically, the QT interval is measured in a lead in which the T wave is prominent, and its end is easily distinguished, such as V1 or V6. Because the QT interval shortens with tachycardia and lengthens with bradycardia, it is typically corrected for heart rate and is noted as QTc.20 Nonetheless, a QTc greater than 440 milliseconds in men and greater than 460 milliseconds in women has been linked with episodes of sudden arrhythmia death syndromes. In addition, T-wave morphology frequently is abnormal in people with LQTS.2

LQTSs have been classified into inherited and acquired forms, both of which are associated with the development of torsade de pointes and sudden cardiac death. The hereditary forms of LQTS are caused by disorders of membrane ion channel proteins, with either potassium channel defects or sodium channel defects.19,29

Acquired LQTS has been linked to a variety of conditions, including cocaine use, exposure to organophosphorus compounds, electrolyte imbalances, marked bradycardia, MI, subarachnoid hemorrhage, autonomic neuropathy, human immunodeficiency virus infection, and protein-sparing fasting.30 Medications linked to LQTS include digitalis, antiarrhythmic agents (e.g., amiodarone, procainamide, and quinidine), verapamil (calcium channel blocker), haloperidol (antipsychotic agent), and erythromycin (antibiotic).20,30 The acquired forms of LQTS often are classified as pause dependent because the torsade de pointes associated with them generally occurs at slow heart rates or in response to short–long–short R-R interval sequences. Treatment of acquired forms of LQTS is directed primarily at identifying and withdrawing the offending agent, although emergency measures that modulate the function of transmembrane ion currents can be lifesaving.

Ventricular Arrhythmias

Arrhythmias that arise in the ventricles generally are considered more serious than those that arise in the atria because they afford the potential for interfering with the pumping action of the heart.

Premature Ventricular Contractions.

A premature ventricular contraction (PVC) is caused by a ventricular ectopic pacemaker. After a PVC occurs, the ventricle usually is unable to repolarize sufficiently to respond to the next impulse that arises in the SA node. This delay, commonly referred to as a compensatory pause, occurs while the
Ventricular arrhythmias. Premature ventricular contractions (PVCs) (top tracing) originate from an ectopic focus in the ventricles, causing a distortion of the QRS complex. Because the ventricle usually cannot repolarize sufficiently to respond to the next impulse that arises in the SA node, a PVC frequently is followed by a compensatory pause. Ventricular tachycardia (middle tracing) is characterized by a rapid ventricular rate of 70 to 250 beats/minute and the absence of P waves. In ventricular fibrillation (bottom tracing), there are no regular or effective ventricular contractions, and the ECG tracing is totally disorganized.

A special pattern of PVC called ventricular bigeminy is a condition in which each normal beat is followed by or paired with a PVC. This pattern often is an indication of digitalis toxicity or heart disease. The occurrence of frequent PVCs in the diseased heart predisposes to the development of other, more serious arrhythmias, including ventricular tachycardia and ventricular fibrillation.

Ventricular Tachycardia. Ventricular tachycardia describes a cardiac rhythm originating distal to the bifurcation of the bundle of His, in the specialized conduction system in ventricular muscle, or both. It is characterized by a ventricular rate of 70 to 250 beats/minute, and the onset can be sudden or insidious. Usually, ventricular tachycardia is exhibited electrocardiographically with wide, tall, bizarre-looking QRS complexes that persist longer than 0.12 second (see Fig. 33.12). QRS complexes can be uniform in appearance, monomorphic, or they can vary randomly, in a repetitive manner (e.g., torsade de pointes), in an alternating pattern (e.g., bidirectional), or in a stable but changing fashion, polymorphic. Ventricular tachycardia can be sustained, lasting more than 30 seconds and requiring intervention, or it can be nonsustained and stop spontaneously. This rhythm is dangerous because it eliminates atrial kick and can cause a reduction in diastolic filling time to the point at which cardiac output is severely diminished or nonexistent.

Ventricular Flutter and Fibrillation. These arrhythmias represent severe derangements of cardiac rhythm that terminate fatally within minutes unless corrective measures are taken promptly. The ECG pattern in ventricular flutter has a sine-wave appearance with large oscillations occurring at a rate of 150 to 300 per minute. In ventricular fibrillation, the ventricle quivers but does not contract. The classic ECG pattern of ventricular fibrillation is that of gross disorganization without identifiable waveforms or intervals (see Fig. 33.12). When the ventricles do not contract, there is no cardiac output, and there are no palpable or audible pulses. Immediate defibrillation using a nonsynchronized, direct-current electrical shock is mandatory for ventricular fibrillation and for ventricular flutter that has caused loss of consciousness.

Disorders of Atrioventricular Conduction

Under normal conditions, the AV junction, which consists of the AV node with its connections to the entering atrial internodal pathways, the AV bundle, and the nonbranching portion of the bundle of His, provides the only connection for transmission of impulses between the atrial and ventricular conduction systems. Functional fibers in the AV node have high-resistance characteristics that cause a delay in the transmission of impulses from the atria to the ventricles. This delay provides optimal timing for the atrial contribution to ventricular filling and protects the ventricles from abnormally rapid rates that arise in the atria. Conduction defects of the AV node are most commonly associated with fibrosis or scar tissue in fibers of the conduction system. Conduction defects also may result from medications, including digoxin, β-adrenergic blocking agents, calcium channel–blocking agents, and class 1A antiarrhythmic agents. Additional contributing factors include electrolyte imbalances, acute MI, idiopathic fibrosis of the conduction system, inflammatory disease, or cardiac surgery. Some other less common causes include infections, autoimmune, oncologic, and iatrogenic disorders.

Heart block refers to abnormalities of impulse conduction. It may be normal, physiologic (e.g., vagal tone), or pathologic. It may occur from a conduction block in the atrium, AV nodal fibers, or in the AV bundle (i.e., bundle of His), which is continuous with the Purkinje conduction system that supplies the ventricles. The PR interval on the ECG corresponds with the time it takes for the cardiac impulse to travel from the SA node to the ventricular pathways. Normally, the PR interval ranges from 0.12 to 0.20 second.

First-Degree AV Block. First-degree AV block is characterized by a prolonged PR interval (>0.20 second; Fig. 33.13). The prolonged PR interval indicates delayed AV conduction,
but all atrial impulses are conducted to the ventricles. This condition usually produces a regular atrial and ventricular rhythm. Clinically significant PR interval prolongation can result from conduction delays in the AV node itself, the His–Purkinje system, or both. When the QRS complex is normal in contour and duration, the AV delay almost always occurs in the AV node and rarely in the bundle of His. In contrast, when the QRS complex is prolonged, showing a bundle branch block pattern, conduction delays may be in the AV node or the His–Purkinje system. First-degree block may be the result from conduction delays in the AV node itself, the His–Purkinje system, or both. When the QRS complex is normal in contour and duration, the AV delay almost always occurs in the AV node and rarely in the bundle of His. In contrast, when the QRS complex is prolonged, showing a bundle branch block pattern, conduction delays may be in the AV node or the His–Purkinje system. First-degree block may be the result from conduction delays in the AV node, such as ischemia or infarction, or of infections such as rheumatic fever or myocarditis.19,32 Isolated first-degree heart block usually is not symptomatic, and temporary or permanent cardiac pacing is not indicated, but should be monitored.

**Second-Degree AV Block.** Second-degree AV block is characterized by intermittent failure of conduction of one or more impulses from the atria to the ventricles. The nonconducted P wave can appear intermittently or frequently. A distinguishing feature of second-degree AV block is that conducted P waves relate to QRS complexes with recurring PR intervals; that is, the association of P waves with QRS complexes is not random.17 Second-degree AV block has been divided into two types: type I (i.e., Mobitz type I or Wenckebach phenomenon) and type II (i.e., Mobitz type II). A Mobitz type I AV block is characterized by progressive lengthening of the PR interval until an impulse is blocked and the sequence begins again. It frequently occurs in persons with inferior wall MI, particularly with concomitant right ventricular infarction. The condition usually is associated with an adequate ventricular rate and rarely is symptomatic. It usually is transient and does not require temporary pacing.17 In the Mobitz type II AV block, an intermittent block of atrial impulses occurs, with a constant PR interval (see Fig. 33.13). It frequently accompanies anterior wall MI and can require temporary or permanent pacing. This condition is associated with a high mortality rate. In addition, Mobitz type II AV block is associated with other types of organic heart disease and often progresses to complete heart block.

**Third-Degree AV Block.** Third-degree, or complete AV block, occurs when the conduction link between the atria and ventricles is lost, resulting in atrial and ventricular depolarization being controlled by separate pacemakers (see Fig. 33.13). The atrial pacemaker can be sinus or ectopic in origin. The ventricular pacemaker usually is located just below the region of the block. The atria usually continue to beat at a normal rate, and the ventricles develop their own rate, which normally is slow (30 to 40 beats/minute). The atrial and ventricular rates are regular but dissociated. Third-degree AV block can result from an interruption at the level of the AV node, in the bundle of His, or in the Purkinje system. Third-degree blocks at the level of the AV node usually are congenital, whereas blocks in the Purkinje system usually are acquired. Normal QRS complexes, with rates ranging from 40 to 60 complexes per minute, usually are displayed on the ECG when the block occurs proximal to the bundle of His.

Complete heart block causes a decrease in cardiac output with possible periods of syncope (fainting), known as a *Stokes-Adams attack.*17 Other symptoms include dizziness, fatigue, exercise intolerance, or episodes of acute heart failure.32 Most people with complete heart block require a permanent cardiac pacemaker.

**Inherited Types of Arrhythmias**

Cardiac arrhythmias most commonly occur in the presence of cardiac disease, electrolyte disorders, or other demonstrable abnormalities. Ischemic heart disease is the primary cause for the development of ventricular fibrillation, and structural heart defects such as hypertrophic and dilated cardiomyopathies account for most of the remaining cases. However, in people who for many years were referred to as having *idiopathic ventricular fibrillation,* 30% are unexplained after an autopsy.33 Over the past several decades, considerable evidence has been collected indicating that these cases are genetically determined abnormalities of proteins in the ion channels that control the electrical activity of the heart. At least nine genes have been associated with inherited arrhythmogenic cardiomyopathies, and it is expected that more will be identified and linked to sudden death in people with apparently healthy hearts.33 Among the inherited arrhythmogenic disorders are congenital LQTS, SQTS, Brugada syndrome, and catecholaminergic polymorphic ventricular tachycardia.
Congenital Long QT Syndrome. Congenital LQTS is an inherited arrhythmogenic disease characterized by life-threatening ventricular arrhythmias. Hundreds of gene mutations have been identified on the three major and nine minor LQTS susceptible genes.24 The ECG marker for LQTS consists of a prolonged QT interval, abnormal morphology of the T wave, and a characteristic polymorphic ventricular tachycardia (torsade de pointes). Onset of symptoms is typically in the first two decades of life, including the neonatal period, where it can be misdiagnosed as sudden infant death.33 The severity of the clinical manifestations in LQTS varies, ranging from full-blown disease with marked prolongation of the QT interval and recurrent syncope to subclinical forms with borderline QT-interval prolongation and no arrhythmias or syncopal episodes.

The hereditary forms of LQTS are typically considered adrenergic dependent because they are generally triggered by increased activity of the sympathetic nervous system.35 Depending on which gene is affected, long-term treatment with β-adrenergic receptor blockers, permanent pacing, or left cardiac sympathetic denervation is frequently effective.36 Placement of an implantable cardioverter–defibrillator is recommended for people in whom recurrent syncope, sustained ventricular arrhythmias, or sudden cardiac arrest occurs despite drug treatment.

Short QT Syndrome. Short QT syndrome (SQTS) was first described in 2000 and is associated with a QT interval less than 320 milliseconds. There are still limited data on the syndrome. However, of the research that has been performed, most people with this disorder are asymptomatic and approximately 25% have a history of syncope.33,35 Five SQTS susceptible genes have been discovered, but the correlations are still unclear.

Brugada Syndrome. First described in 1992, Brugada syndrome is an autosomal dominant disorder characterized by ST-segment elevation in precordial leads V1 to V3, right bundle branch block, and susceptibility to ventricular tachycardia.35 It has so far been associated with a single gene encoding for the cardiac sodium channel. The disorder typically manifests in adulthood with very incomplete penetrance, and a high percentage of mutation carriers are asymptomatic.36 Cardiac events typically occur during sleep or rest. Even though the disorder is inherited as an autosomal trait, a male-to-female ratio of 8:1 is observed in clinical manifestations.33

Catecholaminergic Polymorphic Ventricular Tachycardia. Catecholaminergic polymorphic ventricular tachycardia (CPVT) was first described in 1978.35 It was reported that the disorder was characterized by ventricular tachycardia, syncope, and sudden death occurring in familial or sporadic cases in the absence of cardiac disease or ECG abnormalities.

The ECG of people with CPVT is usually remarkably normal with the exception of sinus bradycardia reported in some people. Physical activity and acute emotions are the specific triggers for arrhythmias in people with CPVT. The complexity of the arrhythmias progressively increases with an increase in workload, from isolated premature beats to bigeminy to runs of ventricular tachycardia. Although clinical diagnosis of CPVT is rather elusive because of the absence of abnormal ECG findings, genetic analysis can identify the mutations in approximately 60% of persons with the disorder.37 This is particularly important because if left untreated, the disorder is highly malignant, but the prognosis improves considerably once the disorder is correctly identified and treatment is implemented.36

Antiadrenergic treatment with beta-blockers is the cornerstone of therapy for CPVT. The use of an implantable cardioverter–defibrillator may be necessary when exercise stress testing and Holter monitoring indicate that beta-blockers do not provide complete arrhythmia protection.33

Diagnostic Methods

The diagnosis of cardiac rhythm and conduction disorders usually is made on the basis of the surface ECG, Holter ECG monitoring, or implantable loop ECG recording. Further clarification of conduction defects and cardiac arrhythmias can be obtained using exercise stress testing and electrophysiologic studies.

Surface ECG

A resting surface ECG records the impulses originating in the heart as they are recorded at the body surface. These impulses are recorded for a limited time and during periods of inactivity. Although there are no complications related to the procedure, errors related to misdiagnosis may result in iatrogenic heart disease.1 The resting ECG is the first approach to the clinical diagnosis of disorders of cardiac rhythm and conduction, but it is limited to events that occur during the period the ECG is being monitored.

Signal-averaged ECG is a special type of ECG that is used to detect ventricular late action potentials that are thought to originate from slow-conducting areas of the myocardium.37 Ventricular late action potentials are low-amplitude, high-frequency waveforms in the terminal QRS complex, and they persist for tens of milliseconds into the ST segment. The presence of late potentials indicates high risk for development of ventricular tachycardia and sudden cardiac death. These late potentials are detectable from leads of the surface ECG when signal averaging is performed.

The intent of signal averaging is reduction of noise that makes surface ECG analysis more difficult to interpret. This technique averages multiple samples of QRS waveforms and creates a tracing that is an average of all the repetitive signals. A high-pass filtering is used to record the late potentials. As a result, when several inputs that represent the same event are combined, the coherent signal will be reinforced and the noise will cancel itself.

Signal averaging is a computer-based process. Each electrode input is amplified, its voltage is sampled or measured at intervals of 1 millisecond or less, and each sample...
is converted into a digital number. The ECG waveform is converted from an analog waveform to digital numbers that become a computer-readable ECG.

**Holter ECG Monitoring**
Holter monitoring is one form of long-term monitoring during which a person wears a device that digitally records two or three ECG leads for up to 48 hours. During this time, the person keeps a diary of his or her activities or symptoms, which later are correlated with the ECG recording. Most recording devices also have an event marker button that can be pressed when the individual experiences symptoms, which assists the technician or physician in correlating the diary, symptoms, and ECG changes during analysis. Newer Holter recorders are capable of providing a derived 12-lead ECG. Holter monitoring is useful for documenting arrhythmias, conduction abnormalities, and ST-segment changes. The interpretative accuracy of long-term Holter recordings varies with the system used and clinician expertise. Most computer software packages used to scan Holter recordings are sufficiently accurate to meet clinical demand. The majority of patients who have ischemic heart disease exhibit PVCs, particularly those who have recently experienced MI. The frequency of PVCs increases progressively over the first several weeks and decreases approximately 6 months postinfarction. Holter recordings also are used to determine antiarrhythmic drug efficacy, episodes of myocardial ischemia, QT prolongation, and heart rate variability.

Intermittent ECG recorders, event recorders, also are used in the diagnosis of arrhythmias and conduction defects. There are two basic types of recorders that perform this type of monitoring. The first continuously monitors rhythm and is programmed to recognize abnormalities. In the second variety, the unit does not continuously monitor the ECG and therefore cannot automatically recognize abnormalities. The latter form relies on the person to activate the unit when he or she is symptomatic. The data are stored in memory or transmitted telephonically to an ECG receiver, where they are recorded. These types of ECG recordings are useful in people who have transient symptoms and used up to 30 days.

**Implantable Loop ECG Recorder**
If Holter and event monitors do not produce any diagnostic information, a loop recorder can be implanted. This device is implanted under the skin in the left upper chest area. It continuously monitors the person’s ECG and can be programmed to store patient-activated events when they are symptomatic. The loop recorder can be in place for as long as 1 year. It is useful for documenting arrhythmias, antiarrhythmic drug efficacy, episodes of myocardial ischemia, QT prolongation, heart rate turbulence, and heart rate variability.

**Exercise Stress Testing**
The exercise stress test elicits the body’s response to measured increases in acute exercise. This technique provides information about changes in heart rate, blood pressure, respiration, and perceived level of exercise. It is useful in determining exercise-induced alterations in hemodynamic response and ECG ischemic-type ST-segment changes and can detect and classify disturbances in cardiac rhythm and conduction associated with exercise. These changes are indicative of a poorer prognosis in people with known coronary disease and recent MI.

**Electrophysiologic Studies**
Electrophysiologic testing is used for the diagnosis and management of complex arrhythmias. It involves the passage of two or more electrode catheters into the right side of the heart. These catheters are inserted into the femoral, subclavian, internal jugular, or antecubital veins and positioned with fluoroscopy into the high right atrium near the sinus node, the area of the His bundle, the coronary sinus that lies in the posterior AV groove, and into the right ventricle. The electrode catheters are used to stimulate the heart and record intracardiac ECGs. During the study, overdrive pacing, cardioversion, or defibrillation may be necessary to terminate tachycardia induced during the stimulation procedures.

The primary indications for electrophysiologic testing are:

- To determine a person’s potential for arrhythmia formation
- To evaluate recurrent syncope of cardiac origin, when ambulatory ECG has not provided the diagnosis
- To differentiate supraventricular from ventricular arrhythmias
- To locate arrhythmogenic foci for therapeutic interventions such as catheter ablation procedures or antitachycardia devices.

Testing can also define reproducible arrhythmia induction characteristics and hence can be used to evaluate the therapeutic efficacy of a particular treatment modality.

Electrophysiologic methods can also be used as interventions. These interventions may include pacing a person out of tachycardia or ablation therapy. Ablation therapy involves the destruction of myocardial tissue by delivering electrical energy over electrodes on a catheter placed next to an area related to the onset or maintenance of arrhythmias.

Risks associated with electrophysiologic testing are small. Most electrophysiologic studies do not involve left-sided heart access, and therefore, the risk of MI, stroke, or systemic embolism is less than observed with coronary arteriography. The addition of therapeutic maneuvers, such as ablation therapy, to the procedure increases the risk of complications, which include venous thrombosis and pulmonary emboli.

**Treatment**
The treatment of cardiac rhythm or conduction disorders is directed toward controlling the arrhythmia, correcting the cause, and preventing more serious or fatal arrhythmias. Correction may involve simply adjusting an electrolyte disturbance or withholding a medication such as digitalis. Preventing more serious arrhythmias often involves drug therapy, electrical stimulation, or surgical intervention.
Pharmacologic Treatment

Antiarrhythmic drugs act by modifying the disordered formation and conduction of impulses that induce cardiac muscle contraction. These drugs are classified into four major groups (class I through class IV) according to the drug’s effect on the action potential of the cardiac cells. Although drugs in one category have similar effects on conduction, they may vary significantly in their hemodynamic effects. Two other types of antiarrhythmic drugs, the cardiac glycosides and adenosine, are not included in this classification schema. The cardiac glycosides (i.e., digitalis drugs) slow the heart rate and are used in the management of arrhythmias such as atrial tachycardia, atrial flutter, and AF. Adenosine, an endogenous nucleoside that is present in every cell, is used for emergency intravenous treatment of paroxysmal supraventricular tachycardia involving the AV node. It interrupts AV node conduction and slows SA node firing.

Class I Drugs. Class I drugs act by blocking the fast sodium channels. These drugs affect impulse conduction, excitability, and automaticity to various degrees and therefore have been divided further into three groups: IA, IB, and IC. Class IA drugs (e.g., quinidine, procainamide, disopyramide) decrease automaticity by depressing phase 4 of the action potential, decrease conductivity by moderately prolonging phase 0, and prolong repolarization by extending phase 3 of the action potential. Because these drugs are effective in suppressing ectopic foci and treating reentrant arrhythmias, they are used for supraventricular and ventricular arrhythmias. Class IB drugs (e.g., lidocaine, mexiletine) decrease automaticity by depressing phase 4 of the action potential, have little effect on conductivity, decrease refractoriness by decreasing phase 2, and shorten repolarization by decreasing phase 3. These drugs have little or no effect on sodium channels in resting cells. However, they shorten the action potential and are powerful inhibitors of sodium-dependent conduction in depolarized cells, making them effective in depressing conduction in ischemic areas of the heart. Drugs in this group are used for treating ventricular arrhythmias only and have little or no effect on myocardial contractility. Class IC drugs (e.g., propafenone, moricizine, flecainide) decrease conductivity by markedly depressing phase 0 of the action potential but have little effect on refractoriness or repolarization. Their primary action is inhibition of sodium channel opening. Drugs in this class are used for life-threatening ventricular arrhythmias and supraventricular tachycardias.

Class II Drugs. Class II drugs (e.g., propranolol, metoprolol, atenolol, timolol, sotalol) are β-adrenergic blocking drugs that act by blunting the effect of sympathetic nervous system stimulation on the heart, thereby inhibiting calcium channel opening. These drugs decrease automaticity by depressing phase 4 of the action potential. They also decrease heart rate and cardiac contractility. These medications are effective for treatment of supraventricular arrhythmias and tachyarrhythmias by counteracting action on arrhythmogenesis of catecholamines. However, these drugs are not very effective in treating severe arrhythmias, such as recurrent ventricular tachycardia.

Class III Drugs. Class III drugs (e.g., amiodarone, bretylium, ibutilide, dofetilide, sotalol) act by inhibiting the potassium current and repolarization, thereby extending the action potential and refractoriness. They have little inhibiting effect on depolarizing currents. Sotalol has both β-adrenergic receptor blocking (class II) and action potential prolonging (class III) actions. It may cause QT prolongation and should be discontinued if there is a greater than 15% increase from baseline. Sotalol is used to treat AF and ventricular tachycardia related to old MI. Amiodarone not only can cause QT prolongation, but it has additional extracardiac side effects such as thyroid, hepatic, and pulmonary toxicities. These toxicities need to be monitored on a regular basis and taken into account when deciding to initiate treatment for AF and ventricular arrhythmias. Dofetilide is used for the treatment of AF and flutter as well as to prevent recurrences and control rate. Unlike amiodarone, it does not have associated toxicities, but it does prolong the QT interval. Ibutilide may also cause QT prolongation, but this prolongation returns to normal in 3 to 4 hours after the infusion is discontinued. These agents are used in the treatment of serious ventricular arrhythmias.

Class IV Drugs. Class IV drugs (e.g., verapamil, diltiazem, mibefradil) act by blocking the slow calcium channels, thereby depressing phase 4 and lengthening phases 1 and 2 of the action potential. By blocking the release of intracellular calcium ions, these agents reduce the force of myocardial contractility, thereby decreasing myocardial oxygen demand. These drugs are used to slow the SA node pacemaker and inhibit conduction in the AV node, slowing the ventricular response in atrial tachycardias, and to terminate reentrant paroxysmal supraventricular tachycardias when the AV node functions as a reentrant pathway.

Electrical Interventions

The correction of conduction defects, bradyarrhythmias, and tachyarrhythmias can involve the use of a pacemaker, cardioversion, or defibrillation. Electrical interventions can be used in emergency and elective situations. Efforts directed at cardiac electrostimulation date back more than a century. During this time, tremendous strides have been made in the effectiveness of cardiac pacing.

Cardiac Pacemaker. A cardiac pacemaker is an electronic device that delivers an electrical stimulus to the heart. It is used to initiate heartbeats in situations when the normal pacemaker of the heart is defective. These situations include certain types of AV heart block, symptomatic bradyarrhythmias in which the rate of cardiac contraction and consequent cardiac output are inadequate to perfuse vital tissues, as well as other cardiac arrhythmias. A pacemaker may be used as a temporary or a permanent measure. Pacemaker leads
can pace the atria, the ventricles, or the atria and ventricles sequentially, or overdrive pacing can be used. Overdrive pacing is used to treat recurrent ventricular tachycardia and reentrant atrial or ventricular tachyarrhythmias and to terminate atrial flutter.

Temporary pacemakers are useful for treatment of symptomatic bradycardias and to perform overdrive pacing. They can be placed transcutaneously, transvenously, or epicardially. External temporary pacing, also known as transcutaneous pacing, involves the placement of large patch electrodes on the anterior and posterior chest wall, which then are connected by a cable to an external pulse generator. Many defibrillators today have transcutaneous pacing capabilities.

Internal temporary pacing, also known as transvenous pacing, involves the passage of a venous catheter with electrodes on its tip into the right atrium or ventricle, where it is wedged against the endocardium. The electrode then is attached to an external pulse generator. This procedure is performed under fluoroscopic or electrocardiographic direction. During open thoracotomy procedures, epicardial pacing wires sometimes are placed. These wires are brought out directly through the chest wall and also can be attached to an external pulse generator, if necessary.

Permanent cardiac pacemakers may become necessary for a variety of reasons. Permanent pacemakers require a pulse generator and implantation of pacing wires into the epicardium that deliver the electrical stimuli. Ongoing evaluation of the pacemaker’s sensing, firing, and battery life is necessary on a regular basis.

**Synchronized Cardioversion and Defibrillation.** Synchronized cardioversion and defibrillation are two reliable methods for treating ventricular tachycardia, and cardioversion is the definitive treatment for AF. The discharge of electrical energy that is synchronized with the R wave of the ECG is referred to as synchronized cardioversion, and unsynchronized discharge is known as defibrillation. The goal of both of these techniques is to provide an electrical pulse to the heart in such a way as to depolarize the heart completely during passage of the current. This electrical current interrupts the disorganized impulses, allowing the SA node to regain control of the heart. Defibrillation and synchronized cardioversion can be delivered externally through large patch electrodes on the chest or internally through small paddle electrodes placed directly on the myocardium, patch electrodes sewn into the epicardium, or transvenous wires placed in the right ventricle. Electrical devices that combine anti-tachycardia pacing, cardioversion, defibrillation, and bradycardial pacing are under investigation.

Automatic implantable cardioverter–defibrillators (AICDs) are being used successfully to treat individuals with life-threatening ventricular tachyarrhythmias by the use of intrathoracic electrical countershock. Reliable sensing and detection of ventricular tachyarrhythmias are essential for proper functioning of the AICD. Sensing and detection are accomplished through endocardial leads. The AICD responds to ventricular tachyarrhythmia by delivering an electrical shock between intrathoracic electrodes within 10 to 20 seconds of its onset. This time frame provides nearly a 100% likelihood of reversal of the arrhythmia, supporting the utility of this device as a reliable and effective means of preventing sudden cardiac death in survivors of out-of-hospital cardiac arrest.

**Ablation and Surgical Interventions**

Ablation therapy is used for treating recurrent, life-threatening supraventricular and ventricular tachyarrhythmias. Ablative therapy may be performed by catheter or surgical techniques. It involves localized destruction, isolation, or excision of cardiac tissue that is considered to be arrhythmogenic.

The first catheter ablation procedures were performed using direct-current shocks, but this energy source has largely been replaced by radiofrequency (RF) energy, which is delivered by an external generator and destroys tissue by heat production. RF ablation uses RF waves to destroy defective or aberrant electrical conduction pathways. Cryoablation involves the direct application of an extremely cold probe to arrhythmogenic cardiac tissue. Catheter-delivered cryoablation causes damage by freezing cellular structures of defective or aberrant electrical conduction pathways.

Additional surgical interventions such as coronary artery bypass surgery, ventriculotomy, and endocardial resection may be used to improve myocardial oxygenation, remove arrhythmogenic foci, or alter electrical conduction pathways. Coronary artery bypass surgery improves myocardial oxygenation by increasing blood supply to the myocardium. Ventriculotomy involves the removal of aneurysm tissue and the resuturing of the myocardial walls to eliminate the paradoxical ventricular movement and the foci of arrhythmias. In endocardial resection, endocardial tissue that has been identified as arrhythmogenic through the use of electrophysiologic testing or intraoperative mapping is surgically removed. Ventriculotomy and endocardial resection have been performed with cryoablation or laser ablation as an adjunctive therapy.

**IN SUMMARY**

Disorders of cardiac rhythm arise as the result of disturbances in impulse generation or conduction in the heart. Normal sinus rhythm and respiratory sinus arrhythmia (i.e., heart rate speeds up and slows down in concert with the respiratory cycle) are considered normal cardiac rhythms. Cardiac arrhythmias are not necessarily pathologic; they occur in healthy and diseased hearts. Sinus arrhythmias originate in the SA node. They include sinus bradycardia (heart rate <60 beats/minute); sinus tachycardia (heart rate >100 beats/minute); sinus arrest, in which there are prolonged periods of asystole; and sick sinus syndrome, a condition characterized by periods of bradycardia alternating with tachycardia.

Atrial arrhythmias arise from alterations in impulse generation that occur in the conduction pathways or muscle of the atria. They include PACs, atrial flutter...
(i.e., atrial depolarization rate of 240 to 450 beats/minute), and AF (i.e., grossly disorganized atrial depolarization that is irregular with regard to rate and rhythm). Atrial arrhythmias often go unnoticed unless they are transmitted to the ventricles.

Arrhythmias that arise in the ventricles commonly are considered more serious than those that arise in the atria because they afford the potential for interfering with the pumping action of the heart. The LQTS represents a prolongation of the QT interval that may result in torsade de pointes and sudden cardiac death. A PVC is caused by a ventricular ectopic pacemaker. Ventricular tachycardia is characterized by a ventricular rate of 70 to 250 beats/minute. Ventricular fibrillation (e.g., ventricular rate >350 beats/minute) is a fatal arrhythmia unless it is successfully treated with defibrillation. Arrhythmogenic cardiomyopathies are inherited disorders of the ion channels that control the electrical activity of the heart. Among the inherited arrhythmogenic disorders are congenital LQTS, SQTS, Brugada syndrome, and catecholaminergic polymorphic ventricular tachycardia.

Alterations in the conduction of impulses through the AV node lead to disturbances in the transmission of impulses from the atria to the ventricles. There can be a delay in transmission (i.e., first-degree heart block), failure to conduct one or more impulses (i.e., second-degree heart block), or complete failure to conduct impulses between the atria and the ventricles (i.e., third-degree heart block). Conduction disorders of the bundle of His and Purkinje system, called bundle branch blocks, cause a widening of and changes in the configuration of the QRS complex of the ECG.

The diagnosis of disorders of cardiac rhythm and conduction typically is accomplished using surface ECG recordings or electrophysiological studies. Surface electrodes can be used to obtain a 12-lead ECG; signal-averaged electrocardiographic studies in which multiple samples of QRS waves are averaged to detect ventricular late action potentials; and Holter monitoring, which provides continuous ECG recordings for up to 48 hours and loop recording, which provides continuous recording up to 1 year. Electrophysiological studies use electrode catheters inserted into the right heart through a peripheral vein as a means of directly stimulating the heart while obtaining an intracardiac ECG recording.

Both medications and electrical devices are used in the treatment of arrhythmias and conduction disorders. Antiarrhythmic drugs act by modifying disordered formation and conduction of impulses that induce cardiac muscle contraction. They include drugs that act by blocking the fast sodium channels, β-adrenergic blocking drugs that decrease sympathetic outflow to the heart, drugs that act by inhibiting the potassium current and repolarization, calcium channel-blocking agents, cardiac glycosides (i.e., digitalis drugs), and adenosine, which is used for emergency intravenous treatment of paroxysmal supraventricular tachycardia involving the AV node. Electrical devices include temporary and permanent cardiac pacemakers that are used to treat symptomatic bradycardias or to provide overdrive pacing procedures; defibrillators that are used to treat atrial and ventricular fibrillation; external or internally implanted cardioversion devices, which can be used to treat ventricular tachycardia; and RF ablation and cryoablation therapy, which are used to destroy specific irritable foci in the heart. Surgical procedures can be performed to excise irritable or dysfunctional tissue, to replace cardiac valves, or to provide better blood supply to the myocardial muscle wall.

**REVIEW EXERCISES**

1. A 75-year-old woman with a history of congestive heart failure comes to the clinic complaining of feeling tired. Her heart rate is 121 beats/minute, and the rhythm is irregular.
   A. What type of arrhythmia do you think she might be having? What would it look like if you were to obtain an ECG?
   B. What causes this irregularity?
   C. Why do you think she is feeling tired?
   D. What are some of the concerns with this type of arrhythmia?

2. A 45-year-old man appears at the urgent care center with complaints of chest discomfort, shortness of breath, and generally not feeling well. You assess vital signs and find that his temperature is 99.2°F, blood pressure 180/90, pulse 90 and slightly irregular, and respiratory rate 26. You do an ECG, and the readings from the anterior leads indicate that he is experiencing an ischemic episode.
   A. You attach him to a cardiac monitor and see that his underlying rhythm is normal sinus rhythm, but he is having frequent premature contractions that are more than 0.10 sec in duration. What type of premature contractions do you suspect?
   B. What would you expect his pulse to feel like?
   C. What do you think the etiology of this arrhythmia might be? How might it be treated?

Adequate perfusion of body tissues depends on the pumping ability of the heart, a vascular system that transports blood to the cells and back to the heart, sufficient blood to fill the circulatory system, and tissues that are able to extract and use oxygen and nutrients from the blood. Heart failure and circulatory shock are separate conditions that reflect failure of the circulatory system. Both conditions exhibit common compensatory mechanisms even though they differ in terms of pathogenesis and causes.
the incidence of heart failure is increasing at an alarming rate. Approximately 400,000 to 700,000 people are diagnosed with heart failure each year.

The syndrome of heart failure can be produced by any heart condition that reduces the pumping ability of the heart. Among the most common causes of heart failure are coronary artery disease, hypertension, dilated cardiomyopathy, and valvular heart disease. Because many of the processes leading to heart failure are long-standing and progress gradually, heart failure can often be prevented or its progression slowed by early detection and intervention. The importance of these approaches is emphasized by the American College of Cardiology (ACC)/American Heart Association (AHA) guidelines that have incorporated a classification system of heart failure that includes four stages:

1. Stage A—High risk for developing heart failure, but no identified structural abnormalities and no signs of heart failure
2. Stage B—Presence of structural heart disease, but no history of sign and symptoms of heart failure
3. Stage C—Current or prior symptoms of heart failure with structural heart disease
4. Stage D—Advanced structural heart disease and symptoms of heart failure at rest on maximum medical therapy

This staging system recognizes that there are established risk factors and structural abnormalities that are characteristic of the four stages of heart failure. People normally progress from one stage to another unless disease progression is slowed or stopped by treatment.

**KEY POINTS**

**HEART FAILURE**

- The function of the heart is to move deoxygenated blood from the venous system through the right heart into the pulmonary circulation, and oxygenated blood from the pulmonary circulation through the left heart and into the arterial circulation.
- Systolic dysfunction represents a decrease in myocardial contractility and an impaired ability to eject blood from the left ventricle, whereas diastolic dysfunction represents an abnormality in ventricular relaxation and filling.

**Pathophysiology of Heart Failure**

Cardiac output is the amount of blood that the ventricles eject each minute. The heart has the amazing capacity to adjust its cardiac output to meet the varying needs of the body. During sleep, the cardiac output declines, and during exercise, it increases markedly. The ability to increase cardiac output during increased activity is called the cardiac reserve. For example, competitive swimmers and long-distance runners have large cardiac reserves. During exercise, the cardiac output of these athletes rapidly increases to as much as five to six times their resting level. In sharp contrast with healthy athletes, people with heart failure often use their cardiac reserve at rest. For them, just climbing a flight of stairs may cause shortness of breath because they have exceeded their cardiac reserve.

**Control of Cardiac Performance and Output**

Cardiac output, which is the major determinant of cardiac performance, reflects how often the heart beats each minute (heart rate) and how much blood it pumps with each beat (stroke volume) and can be expressed as the product of the heart rate and stroke volume (i.e., cardiac output = heart rate × stroke volume). The heart rate is regulated by a balance between the activity of the sympathetic nervous system, which produces an increase in heart rate, and the parasympathetic nervous system, which slows it down, whereas the stroke volume is a function of preload, afterload, and myocardial contractility.

**Preload and Afterload.** The work that the heart performs consists mainly of ejecting blood that has returned to the ventricles during diastole into the pulmonary or systemic circulation. It is determined largely by the loading conditions, or what are called the preload and afterload.

**Preload** reflects the volume or loading conditions of the ventricle at the end of diastole, just before the onset of systole. It is the volume of blood stretching the heart muscle at the end of diastole and is normally determined by the venous return to the heart. During any given cardiac cycle, the maximum volume of blood filling the ventricle is present at the end of diastole. Known as the end-diastolic volume, this volume causes an increase in the length of the myocardial muscle fibers. Within limits, as end-diastolic volume or preload increases, the stroke volume increases in accord with the Frank-Starling mechanism.

**Afterload** represents the force that the contracting heart muscle must generate to eject blood from the filled heart. The main components of afterload are the systemic (peripheral) vascular resistance and ventricular wall tension. When the systemic vascular resistance is elevated, as with arterial hypertension, an increased left intraventricular pressure must be generated to first open the aortic valve and then move blood out of the ventricle and into the systemic circulation. This increased pressure equates to an increase in ventricular wall stress or tension. As a result, excessive afterload may impair ventricular ejection and increase wall tension.

**Myocardial Contractility.** Myocardial contractility, also known as inotropy, refers to the contractile performance of the heart. It represents the ability of the contractile elements (actin and myosin filaments) of the heart muscle to interact and shorten against a load. Contractility increases cardiac output independent of preload and afterload.
The interaction between the actin and myosin filaments during cardiac muscle contraction (i.e., cross-bridge attachment and detachment) requires the use of energy supplied by the breakdown of adenosine triphosphate (ATP) and the presence of calcium ions (Ca\(^{++}\)). ATP provides the energy needed for cross-bridge formation during cardiac muscle contraction and for cross-bridge detachment during muscle relaxation.

As with skeletal muscle, when an action potential passes over the cardiac muscle fiber, the impulse spreads to the interior of the muscle fiber along the membranes of the transverse (T) tubules. The T tubule action potentials in turn act to cause release of Ca\(^{++}\) from the sarcoplasmic reticulum (Fig. 34.1). These Ca\(^{++}\) ions diffuse into the myofibrils and catalyze the chemical reactions that promote sliding of the actin and myosin filaments along one another to produce muscle shortening. In addition to the Ca\(^{++}\) ions released from the sarcoplasmic reticulum, a large quantity of extracellular Ca\(^{++}\) also diffuses into the sarcoplasm through voltage-dependent L-type Ca\(^{++}\) channels in T tubules at the time of the action potential. Without the extra Ca\(^{++}\) that enters through the L-type Ca\(^{++}\) channels, the strength of the cardiac contraction would be considerably weaker. Opening of the L-type Ca\(^{++}\) channels is facilitated by the second messenger cyclic adenosine monophosphate (cAMP), the formation of which is coupled to \(\beta\)-adrenergic receptors. The catecholamines (norepinephrine and epinephrine) exert their inotropic effects by binding to these receptors. The L-type calcium channel also contains several other types of drug receptors. The dihydropyridine Ca\(^{++}\) channel blocking drugs (e.g., nifedipine) exert their effects by binding to one site, while diltiazem and verapamil appear to bind to closely related but not identical receptors in another region. Blockade of the Ca\(^{++}\) channels in cardiac muscle by these drugs results in a reduction in contractility throughout the heart and a decrease in sinus node pacemaker rate and in atrioventricular node conduction velocity.

Another mechanism that can modulate inotropy is the sodium ion (Na\(^{+}\)/Ca\(^{++}\) exchange pump and the ATPase-dependent Ca\(^{++}\) pump on the myocardial cell membrane (see Fig. 34.1). These pumps transport Ca\(^{++}\) out of the cell, thereby preventing the cell from becoming overloaded with Ca\(^{++}\). If Ca\(^{++}\) extrusion is inhibited, the rise in intracellular Ca\(^{++}\) can increase inotropy. Digitalis and related cardiac glycosides are inotropic agents that exert their effects by inhibiting the Na\(^{+}\)/potassium ion (K\(^{+}\))–ATPase pump, which increases

![FIGURE 34.1](image_url)
intracellular Na⁺; this in turn leads to an increase in intracellular Ca²⁺ through the Na⁺/Ca²⁺ exchange pump.

**Systolic versus Diastolic Dysfunction**

Classification separates the pathophysiology of heart failure into systolic and diastolic failure or dysfunction based on the ventricular ejection fraction. Ejection fraction is the percentage of blood pumped out of the ventricles with each contraction. A normal ejection fraction is about 55% to 70%. In systolic ventricular dysfunction, myocardial contractility is impaired, leading to a decrease in the ejection fraction and cardiac output. Diastolic ventricular dysfunction is characterized by a normal ejection fraction but impaired diastolic ventricular relaxation, leading to a decrease in ventricular filling that ultimately causes a decrease in preload, stroke volume, and cardiac output. Many people with heart failure have combined elements of both systolic and diastolic ventricular dysfunction, and the division between systolic and diastolic dysfunction may be somewhat artificial, particularly as it relates to manifestations and treatment. It is important to note that ventricular dysfunction is not synonymous with heart failure. It can, however, lead to heart failure. With both systolic and diastolic ventricular dysfunction, compensatory mechanisms are usually able to maintain adequate resting cardiac function until the later stages of heart failure.

**Systolic Dysfunction.** Systolic dysfunction is primarily defined as a decrease in myocardial contractility, characterized by an ejection fraction of less than 40%. A normal heart ejects approximately 65% of the blood that is present in the ventricle at the end of diastole. In systolic heart failure, the ejection fraction declines progressively with increasing degrees of myocardial dysfunction. In very severe forms of heart failure, the ejection fraction may drop to a single-digit percentage. With a decrease in ejection fraction, there is a resultant increase in end-diastolic volume (preload), ventricular dilation, and ventricular wall tension and a rise in ventricular end-diastolic pressure. The increased volume, added to the normal venous return, leads to an increase in ventricular preload. The rise in preload is thought to be a compensatory mechanism to help maintain stroke volume through the Frank-Starling mechanism despite a drop in ejection fraction. Although it serves as a compensatory mechanism, increased preload can also lead to one of the most deleterious consequences of systolic ventricular dysfunction—accumulation of blood in the atria and the venous system (which empties into the atria), causing pulmonary or peripheral edema.

Systolic dysfunction commonly results from conditions that impair the contractile performance of the heart (e.g., ischemic heart disease and cardiomyopathy), produce a volume overload (e.g., valvular insufficiency and anemia), or generate a pressure overload (e.g., hypertension and valvular stenosis) on the heart. The extent of systolic ventricular dysfunction can be estimated by measuring the cardiac output and ejection fraction and by assessment for manifestations of left-sided heart failure, particularly pulmonary congestion.

**Diastolic Dysfunction.** Although heart failure is commonly associated with impaired systolic function, in approximately 55% of cases systolic function has been preserved and heart failure occurs exclusively on the basis of left ventricular diastolic dysfunction. Although such hearts contract normally, relaxation is abnormal. The abnormal filling of the ventricle compromises cardiac output, especially during exercise. For any given ventricular volume, ventricular pressures are elevated, leading to signs of pulmonary and systemic venous congestion identical to those seen in people with a dilated, poorly contracting heart. The prevalence of diastolic failure increases with age and is higher in women than men and in people with hypertension and atrial fibrillation.

Among the conditions that cause diastolic dysfunction are those that impede expansion of the ventricle (e.g., pericardial effusion, constrictive pericarditis), those that increase wall thickness and reduce chamber size (e.g., myocardial hypertrophy, hypertrophic cardiomyopathy), and those that delay diastolic relaxation (e.g., aging, ischemic heart disease). Aging is often accompanied by a delay in relaxation of the heart during diastole such that diastolic filling begins while the ventricle is still stiff and resistant to stretching to accept an increase in volume. A similar delay occurs in myocardial ischemia, resulting from a lack of energy to break the rigor that forms between the actin and myosin filaments and to move Ca²⁺ out of the cytosol and back into the sarcoplasmic reticulum.

Diastolic function is further influenced by the heart rate, which determines how much time is available for ventricular filling. An increase in heart rate shortens the diastolic filling time. Thus, diastolic dysfunction can be aggravated by tachycardia or an arrhythmia and improved by a reduction in heart rate, which allows the heart to fill over a longer period.

With diastolic dysfunction, blood is unable to move freely into the left ventricle, causing an increase in intraventricular pressure at any given volume. The elevated pressures are transferred from the left ventricle into the left atrium and pulmonary venous system, causing a decrease in lung compliance, which increases the work of breathing and evokes symptoms of dyspnea. Cardiac output is decreased, not because of a reduced ventricular ejection fraction as seen with systolic dysfunction but because of a decrease in the volume (preload) available for adequate cardiac output. Inadequate cardiac output during exercise may lead to fatigue of the legs and the accessory muscles of respiration.

**Right versus Left Ventricular Dysfunction**

Heart failure has been classified according to the side of the heart (right ventricular or left ventricular) that is primarily affected (Fig. 34.2). Although the initial event that leads to heart failure may be primarily right or left ventricular in origin, long-term heart failure usually involves both sides. The pathophysiologic changes that occur in the myocardium itself, including the compensatory responses in conditions like myocardial infarction, are not significantly different between right and left ventricular dysfunction and are not addressed in detail in this section.
**Right Ventricular Dysfunction.** Right-sided heart failure impairs the ability to move deoxygenated blood from the systemic circulation into the pulmonary circulation. Consequently, when the right ventricle fails, there is a reduction in the amount of blood moved forward into the pulmonary circulation and then into the left side of the heart, ultimately causing a reduction of left ventricular cardiac output. Also, if the right ventricle does not move the blood forward, there is accumulation or congestion of blood into the systemic venous system. This causes an increase in right ventricular end-diastolic, right atrial, and systemic venous pressures. A major effect of right-sided heart failure is the development of peripheral edema (see Fig. 34.2). Because of the effects of gravity, the edema is most pronounced in the dependent parts of the body. When the person is in the upright position, edema is seen in the lower extremities; when the person is supine, the edema is seen in the area over the sacrum. The accumulation of edema fluid is evidenced by a gain in weight (i.e., 1 pint [568 mL] of accumulated fluid results in a 1 lb [0.45 kg] weight gain). Daily measurement of weight can be used as a means of assessing fluid accumulation in a person with chronic heart failure. As a rule, a weight gain of more than 2 lb (0.90 kg) in 24 hours or 5 lb (2.27 kg) in 1 week is considered a sign of worsening failure.9

Right-sided heart failure also produces congestion of the viscera. As venous distention progresses, blood backs up in the hepatic veins that drain into the inferior vena cava, and the liver becomes engorged. This may cause hepatomegaly and right upper quadrant pain. In severe and prolonged right-sided failure, liver function is impaired and hepatic cells may die. Congestion of the portal circulation also may lead to engorgement of the spleen and the development of ascites. Congestion of the gastrointestinal tract may interfere with digestion and absorption of nutrients, causing anorexia and abdominal discomfort. The jugular veins, which are above the level of the heart, are normally not visible in the standing position or when sitting with the head at higher than a 30-degree angle. In severe right-sided failure, the external jugular veins become distended and can be visualized when the person is sitting up or standing.

The causes of right ventricular dysfunction include conditions that impede blood flow into the lungs or compromise the pumping effectiveness of the right ventricle. Left ventricular failure is the most common cause of right ventricular failure. Sustained pulmonary hypertension also causes right ventricular dysfunction and failure. Pulmonary hypertension occurs in people with chronic pulmonary disease, severe pneumonia, pulmonary embolus, or aortic or mitral stenosis. When the right heart failure occurs in response to chronic pulmonary disease, it is referred to as cor pulmonale.10 Other common causes include stenosis or regurgitation of the tricuspid or pulmonic valves, right ventricular infarction, and cardiomyopathy. Right ventricular dysfunction with heart failure is also caused by congenital heart defects such as tetralogy of Fallot and ventricular septal defect.

**Left Ventricular Dysfunction.** Left-sided heart failure impairs the movement of blood from the low-pressure pulmonary circulation into the high-pressure arterial side of the
systemic circulation. With impairment of left heart function, there is a decrease in cardiac output to the systemic circulation. Blood accumulates in the left ventricle, left atrium, and pulmonary circulation, which causes an elevation in pulmonary venous pressure (see Fig. 34.2). When the pressure in the pulmonary capillaries (normally approximately 10 mm Hg) exceeds the capillary osmotic pressure (normally approximately 25 mm Hg), there is a shift of intravascular fluid into the interstitium of the lung and development of pulmonary edema (Fig. 34.3). An episode of pulmonary edema often occurs at night, after the person has been reclining for some time and the gravitational forces have been removed from the circulatory system. It is then that the edema fluid that had been sequestered in the lower extremities during the day is returned to the vascular compartment and redistributed to the pulmonary circulation.

The most common causes of left ventricular dysfunction are hypertension and acute myocardial infarction. Left ventricular heart failure and pulmonary congestion can develop very rapidly in people with acute myocardial infarction. Even when the infarcted area is small, there may be a surrounding area of ischemic tissue. This may result in large areas of ventricular wall hypokinesis or akinesis and rapid onset of pulmonary congestion and edema. Stenosis or regurgitation of the aortic or mitral valve also creates the level of left-sided backflow that results in pulmonary congestion. As pulmonary pressure rises as a result of congestion, it may progress to produce right-sided heart failure.

**High-Output versus Low-Output Failure**

High- and low-output heart failures are described in terms of cardiac output. High-output failure is an uncommon type of heart failure that is caused by an excessive need for cardiac output. With high-output failure, the function of the heart may be supranormal but inadequate owing to excessive metabolic needs. Causes of high-output failure include severe anemia, thyrotoxicosis, conditions that cause arteriovenous shunting, and Paget disease.

Low-output failure is caused by disorders that impair the pumping ability of the heart, such as ischemic heart disease and cardiomyopathy. Low-output failure is characterized by clinical evidence of systemic vasoconstriction with cold, pale, and sometimes cyanotic extremities. In advanced forms of low-output failure, marked reductions in stroke volume are evidenced by a narrowing of the pulse pressure. In contrast, in high-output failure, the extremities are usually warm and flushed and the pulse pressure is widened or at least normal.

**Compensatory Mechanisms**

In heart failure, the cardiac reserve is largely maintained through compensatory or adaptive responses such as the Frank-Starling mechanism, activation of neurohumoral influences such as the sympathetic nervous system reflexes, the renin–angiotensin–aldosterone mechanism, NPs, locally produced vasoactive substances, and myocardial hypertrophy and remodeling (Fig. 34.4).

The first of these adaptations occurs rapidly over minutes to hours of myocardial dysfunction and may be adequate to maintain the overall pumping performance of the heart at relatively normal levels. Myocardial hypertrophy and remodeling occur slowly over months to years and play an important role in the long-term adaptation to hemodynamic overload. In the failing heart, early decreases in cardiac function may go unnoticed because these compensatory mechanisms maintain the cardiac output. However, these mechanisms contribute not only to the adaptation of the failing heart but also to the pathophysiology of heart failure.

**Frank-Starling Mechanism.** The Frank-Starling mechanism operates through an increase in preload (Fig. 34.5). With increased diastolic filling, there is increased stretching of the myocardial fibers and more optimal approximation of the heads on the thick myosin filaments to the troponin binding sites on the thin actin filaments, with a resultant increase in
the force of the next contraction. In the normally functioning heart, the Frank-Starling mechanism serves to match the outputs of the two ventricles. As illustrated in Figure 34.5, there is no one single Frank-Starling curve. An increase in contractility, or inotropy, will increase cardiac output at any end-diastolic volume, causing the curve to move up and to the left, whereas a decrease in inotropy will cause the curve to move down and to the right. In heart failure, inotropy is decreased compared with normal. Thus, the stroke volume will not be as high as with normal inotropy, regardless of the increase in preload.

In heart failure, a decrease in cardiac output and renal blood flow leads to increased sodium and water retention, a resultant increase in vascular volume and venous return to the heart, and an increase in ventricular end-diastolic volume. Within limits, as preload and ventricular end-diastolic volume increase, there is a resultant increase in cardiac output. Although this may preserve the resting cardiac output, the resulting chronic elevation of left ventricular end-diastolic pressure is transmitted to the atria and the pulmonary circulation, causing pulmonary congestion.

An increase in muscle stretch, as occurs with the Frank-Starling mechanism, also causes an increase in ventricular wall tension with a resultant increase in myocardial oxygen consumption. Because increased wall tension increases myocardial oxygen requirements, it can produce ischemia and contribute to further impairment of inotropy, moving the Frank-Starling curve farther down and to the right (see Fig. 34.5). In this situation, the increase in preload is no longer contributing to compensation but rather causing heart failure to worsen. The use of diuretics in people with heart failure helps to reduce vascular volume and ventricular filling, thereby unloading the heart and reducing ventricular wall tension.
Sympathetic Nervous System Activity. Stimulation of the sympathetic nervous system plays an important role in the compensatory response to decreased cardiac output and stroke volume. Both cardiac sympathetic tone and catecholamine (epinephrine and norepinephrine) levels are elevated during the late stages of most forms of heart failure. By direct stimulation of heart rate and cardiac contractility, regulation of vascular tone, and enhancement of renal sodium and water retention, the sympathetic nervous system initially helps to maintain perfusion of the various body organs. In people who progress to more severe heart failure, blood is diverted to the more critical cerebral and coronary circulations.

Although the sympathetic nervous system response is meant to augment blood pressure and cardiac output and is the most immediate compensatory mechanism, it can become maladaptive. An increase in sympathetic activity by stimulation of the $\beta$-adrenergic receptors of the heart leads to tachycardia, vasoconstriction, and cardiac arrhythmias. Autely, tachycardia significantly increases the workload of the heart, thus increasing myocardial oxygen demand and leading to cardiac ischemia, myocyte damage, and decreased contractility (inotropy). Cardiac ischemia and cardiomyopathy both contribute to worsening of heart failure. By promoting arrhythmias, the catecholamines released with sympathetic nervous system stimulation also may contribute to the high rate of sudden death seen with heart failure.

There is evidence that prolonged sympathetic stimulation may also lead to desensitization of $\beta$-adrenergic receptors without affecting $\alpha$-adrenergic receptors. Even though circulating norepinephrine levels are increased in people with heart failure, the lack of functioning $\beta$-adrenergic receptors in relation to $\alpha$-adrenergic receptors may lead to vasoconstriction and an increase in systemic vascular resistance. An increase in systemic vascular resistance causes an increase in cardiac afterload and ventricular wall stress, thus increasing myocardial oxygen consumption. Other effects include decreased renal perfusion and additional augmentation of the renin–angiotensin–aldosterone system, as well as decreased blood flow to skin, muscle, and abdominal organs.

Renin–Angiotensin–Aldosterone Mechanism. One of the most important effects of lowered cardiac output in heart failure is a reduction in renal blood flow and glomerular filtration rate, which leads to sodium and water retention. With decreased renal blood flow, there is a progressive increase in renin secretion by the kidneys with parallel increases in circulating levels of angiotensin II. The increased concentration of angiotensin II contributes directly to a generalized and excessive vasoconstriction, as well as facilitating norepinephrine release and inhibiting reuptake of norepinephrine by the sympathetic nervous system.

Angiotensin II also provides a powerful stimulus for aldosterone production by the adrenal cortex. Aldosterone increases tubular reabsorption of sodium, with an accompanying increase in water retention. Because aldosterone is metabolized in the liver, its levels are further increased when heart failure causes liver congestion. Angiotensin II also increases the level of antidiuretic hormone (ADH), which serves as a vasoconstrictor and inhibitor of water excretion. In heart failure, the progressive accumulation of fluid leads to ventricular dilation and increased wall tension. The increased oxygen demand that accompanies increased wall tension eventually outweighs the compensatory Frank-Starling mechanism, reducing inotropy and progressing heart failure.

In addition to their individual effects on sodium and water balance, angiotensin II and aldosterone are also involved in regulating the inflammatory and reparative processes that follow tissue injury. In this capacity, they stimulate inflammatory cytokine production (e.g., tumor necrosis factor [TNF] and interleukin-6), attract inflammatory cells (e.g., neutrophils and macrophages), activate macrophages at sites of injury and repair, and stimulate the growth of fibroblasts and synthesis of collagen fibers. Fibroblast and collagen deposition results in ventricular hypertrophy and myocardial wall fibrosis, which decreases compliance (i.e., increases stiffness), ultimately causing inappropriate remodeling of the heart and progression of both systolic and diastolic ventricular dysfunction. Thus, the progression of heart failure may be augmented by aldosterone-mediated effects on both the vasculature and myocardium.

Natriuretic Peptides. The heart muscle produces and secretes a family of related peptide hormones, the cardiac natriuretic hormones or NPs, that have potent diuretic, natriuretic, and vascular smooth muscle effects and also interact with other neurohumoral mechanisms that affect cardiovascular function. Two of the four known NPs most commonly associated with heart failure are atrial natriuretic peptide (ANP) and brain natriuretic peptide (BNP).

As the name indicates, ANP is released from atrial cells in response to atrial stretch, pressure, or fluid overload. BNP is primarily secreted by the ventricles as a response to increased ventricular pressure or fluid overload. In early heart failure, NT-proBNP can be detected as a precursor for BNP in the blood. Although the NPs are not secreted from the same chambers in the heart, they have very similar functions. In response to increased chamber stretch and pressure, they promote rapid and transient natriuresis and diuresis through an increase in the glomerular filtration rate and an inhibition of tubular sodium and water reabsorption.

The NPs also facilitate complex interactions with the neurohormonal system, inhibiting the sympathetic nervous system, the renin–angiotensin–aldosterone system, endothelin inflammatory cytokines, and vasopressin. Suppression of the sympathetic nervous system causes both venous and arterial dilation with consequent reduction in venous return to the heart (decreased preload) and cardiac filling pressures, and a decrease in afterload (arterial vasodilation). Inhibition of angiotensin II and vasopressin by the NPs reduces renal fluid retention. In addition, the NPs directly affect the central nervous system and the brain, inhibiting the secretion of vasopressin and the function of the salt appetite and thirst center.
Circulating levels of both ANP and BNP are reportedly elevated in people with heart failure. BNP and NT-pro BNP levels can be detected through blood work and commercial assays. The concentrations are well correlated with the extent of ventricular dysfunction, increasing up to 30-fold in people with advanced heart disease. Assays of BNP are used clinically in the diagnosis of heart failure and to predict the severity of the condition. Many of the medications used to treat heart failure (e.g., diuretics, such as spironolactone, and the angiotensin-converting enzyme [ACE] inhibitors) reduce BNP concentrations. Therefore, many people with chronic stable heart failure have BNP levels in the normal diagnostic range. However, digoxin and beta-blockers appear to increase BNP levels. There are drugs designed to inhibit degradation on NPs as a potential for therapy.

**Endothelins.** The endothelins, released from the endothelial cells throughout the circulation, are potent vasoconstrictor peptides. Like angiotensin II, endothelin can also be synthesized and released by a variety of cell types, such as cardiac myocytes. Four endothelin peptides (endothelin-1 [ET-1], ET-2, ET-3, and ET-4) have been identified. However, all of their physiological functions remain unclear. It has been found that the endothelins induce vascular smooth muscle cell proliferation and cardiac myocyte hypertrophy; increase the release of ANP, aldosterone, and catecholamines; and exert antinatriuretic effects on the kidneys. Production of ET-1 is regulated by many factors that are significant for cardiovascular function and have implications for heart failure. For example, it is enhanced by angiotensin II, vasopressin, and norepinephrine and by factors such as shear stress and endothelial stretching. Plasma ET-1 levels also correlate directly with pulmonary vascular resistance, and it is thought that the peptide may play a role in mediating pulmonary hypertension in people with heart failure. There are at least two types of endothelin receptors—type A and type B. Type A receptor is associated with smooth muscle constriction and hypertrophy while Type B receptor is associated with vasodilation. Since ET-1 can act on the heart to cause hypertrophy and sodium and water retention, an endothelin receptor antagonist is now available for use in people with pulmonary arterial hypertension due to severe heart failure.

**Inflammatory Mediators.** There is ongoing research examining the relationship between inflammatory markers, especially C-reactive protein (CRP), and heart failure. Elevated CRP levels have been associated with adverse consequences in people with heart failure. They have also been shown to be predictive of the development of heart failure in high-risk groups. Of particular interest are the interactions between CRP and mediators, such as angiotensin II and norepinephrine. This inflammatory relationship continues to be examined. However, it is difficult to test since it is not understood how to decrease the inflammatory effect in heart failure.

**Myocardial Hypertrophy and Remodeling.** The development of myocardial hypertrophy constitutes one of the principal mechanisms by which the heart compensates for an increase in workload. Although ventricular hypertrophy improves the work performance of the heart, it is also an important risk factor for subsequent cardiac morbidity and mortality. Inappropriate hypertrophy and remodeling can result in changes in structure (i.e., muscle mass, chamber dilation) and function (i.e., impaired systolic or diastolic function) that often lead to further pump dysfunction and hemodynamic overload.

Myocardial hypertrophy and remodeling involve a series of complex events at both the molecular and cellular levels. The myocardium is composed of myocytes, or muscle cells, and nonmyocytes. The myocytes are the functional units of cardiac muscle. Their growth is limited by an increment in cell size, as opposed to an increase in cell number. The nonmyocytes include cardiac macrophages, fibroblasts, vascular smooth muscle, and endothelial cells. These cells, which are present in the interstitial space, remain capable of an increase in cell number and provide support for the myocytes. The nonmyocytes also determine many of the inappropriate changes that occur during myocardial hypertrophy. For example, uncontrolled cardiac fibroblast growth is associated with increased synthesis of collagen fibers, myocardial fibrosis, and ventricular wall stiffness. Not only does ventricular wall stiffness increase the workload of the heart, but the fibrosis and remodeling that occur may lead to electrical conduction abnormalities in which the heart contracts in an uncoordinated manner, known as *cardiac dyssynchrony*, causing reduced systolic heart function.

Recent research has focused on the type of hypertrophy that develops in people with heart failure. At the cellular level, cardiac muscle cells respond to stimuli from stress placed on the ventricular wall by pressure and volume overload by initiating several different processes that lead to hypertrophy. These include stimuli that produce the following:

- **Symmetric hypertrophy** with a proportionate increase in muscle length and width, as occurs in athletes
- **Concentric hypertrophy** with an increase in wall thickness, as occurs in hypertension
- **Eccentric hypertrophy** with a disproportionate increase in muscle length, as occurs in dilated cardiomyopathy

(Fig. 34.6)

When the primary stimulus for hypertrophy is *pressure overload*, the increase in wall stress leads to parallel replication of myofibrils, thickening of the individual myocytes, and concentric hypertrophy. Concentric hypertrophy may preserve systolic function for a time, but eventually the work performed by the ventricle exceeds the vascular reserve, predisposing to ischemia. When the primary stimulus is *ventricular volume overload*, the increase in wall stress leads to replication of myofibrils in series, elongation of the cardiac muscle cells, and eccentric hypertrophy. Eccentric hypertrophy leads
to a decrease in ventricular wall thickness with an increase in diastolic volume and wall tension.

**Acute Heart Failure Syndromes**

The acute heart failure syndromes (AHFS) are “defined as gradual or rapid change in heart failure signs and symptoms resulting in a need for urgent therapy.” These symptoms are primarily the result of severe pulmonary edema due to elevated left ventricular filling pressures, with or without a low cardiac output. The syndromes are among the most common disorders seen in emergency departments, and chronic heart failure, often complicated by episodes of acute worsening, is the most common cause of the syndrome.

AHFS are thought to encompass three different types of conditions:

1. Worsening of chronic systolic or diastolic dysfunction that appears to respond to treatment, approximately 80%
2. New-onset acute heart failure that occurs secondary to a precipitating event such as a large myocardial infarction or a sudden increase in blood pressure superimposed on a noncompliant left ventricle
3. Worsening of end-stage/advanced heart failure that is refractory to treatment, with predominantly left ventricular systolic dysfunction associated with a low-output state

The difference between new-onset AHFS and AHFS caused by chronic heart failure is in the degree of physiologic response, which is more pronounced in the new-onset AHFS and subtler in chronic heart failure because of the compensatory pathophysiology. For example, with new-onset AHFS, the person will have a stronger sympathetic response with enhanced pulmonary vascular permeability causing rapid and dramatic symptoms of pulmonary edema. Because many compensatory mechanisms operate in people with chronic heart failure, they tolerate higher pulmonary vascular pressures. Chronic changes in neurohormonal regulation lead to stronger activation of the angiotensin–aldosterone system with a resultant volume overload, and venous congestion is more prominent in both the systemic and pulmonary circulations.

**Clinical Manifestations of Heart Failure**

The manifestations of heart failure depend on the extent and type of cardiac dysfunction that is present and the rapidity with which it develops. A person with previously stable compensated heart failure may develop signs of heart failure for the first time when the condition has advanced to a critical point, such as with a progressive increase in pulmonary hypertension in a person with mitral valve regurgitation. Overt heart failure also may be precipitated by conditions such as infection, emotional stress, uncontrolled hypertension, or fluid overload. Many people with serious underlying heart disease, regardless of whether they have previously experienced heart failure, may be relatively asymptomatic as long they carefully adhere to their treatment regimen. A dietary excess of sodium is a frequent cause of sudden cardiac decompensation.

The manifestations of heart failure reflect the physiologic effects of the impaired pumping ability of the heart, decreased renal blood flow, and activation of the sympathetic compensatory mechanisms. The severity and progression of symptoms depend on the extent and type of dysfunction that is present (systolic versus diastolic, right- versus left-sided). The signs and symptoms include shortness of breath and other respiratory manifestations, fatigue and limited exercise tolerance, fluid retention and edema, cachexia and malnutrition, and cyanosis. People with severe heart failure may exhibit diaphoresis and tachycardia.

**Respiratory Manifestations**

Shortness of breath due to congestion of the pulmonary circulation is one of the major manifestations of left-sided heart failure. Perceived shortness of breath (i.e., breathlessness) is called dyspnea. Dyspnea related to an increase in activity is called exertional dyspnea. Orthopnea is shortness of breath that occurs when a person is supine. Gravitational forces cause fluid to become sequestered in the lower legs and feet when the person is standing or sitting. When the person assumes the recumbent position, fluid from the legs and dependent parts of the body is mobilized and redistributed to an already distended pulmonary circulation. Paroxysmal nocturnal dyspnea is a sudden attack of dyspnea that occurs during sleep. It disrupts sleep, and the person awakens with a feeling of extreme
suffocation that resolves when he or she sits up. Initially, the experience may be interpreted as awakening from a bad dream.

A subtle and often overlooked symptom of heart failure is a chronic dry, nonproductive cough that becomes worse when the person is lying down. Bronchospasm due to congestion of the bronchial mucosa may cause wheezing and difficulty in breathing. This condition is sometimes referred to as *cardiac asthma*.7

Cheyne-Stokes Respiration. Cheyne-Stokes respiration is a pattern of periodic breathing characterized by gradual increase in depth (and sometimes rate) of breathing to a maximum, followed by a decrease resulting in apnea. Although no longer associated solely with heart failure, it is recognized as an independent risk factor for worsening of heart failure. It has been suggested that Cheyne-Stokes respirations may not be just a marker for increasing severity of heart failure but may also aggravate it.14 During sleep, Cheyne-Stokes breathing causes recurrent awakening and thereby reduces slow-wave and rapid eye movement (REM) sleep. The recurrent cycling of hypoventilation/apnea and hyperventilation may also increase sympathetic activity and predispose to arrhythmias. Nocturnal oxygen has been seen to improve sleep, exercise tolerance, and cognitive function.

Acute Pulmonary Edema. Acute pulmonary edema is the most dramatic symptom of AHFS. It is a life-threatening condition in which capillary fluid moves into the alveoli.7 The accumulated fluid in the alveoli and airways causes lung stiffness, makes lung expansion more difficult, and impairs the gas exchange function of the lung. With the decreased ability of the lungs to oxygenate the blood, the hemoglobin leaves the pulmonary circulation without being fully oxygenated, resulting in shortness of breath and cyanosis.

The person with severe pulmonary edema is usually seen sitting and gasping for air. The pulse is rapid, the skin is moist and cool, and the lips and nail beds are cyanotic. As the pulmonary edema worsens and oxygen supply to the brain drops, confusion and stupor appear. Dyspnea and air hunger are accompanied by a productive cough with froth (resembling beaten egg whites) and often blood-tinted sputum—the effect of air mixing with the serum albumin and red blood cells that have moved into the alveoli. The movement of air through the alveolar fluid produces fine crepitant sounds called crackles, which can be heard with chest auscultation. As fluid moves into the larger airways, the crackles become louder and coarser.

Fatigue, Weakness, and Mental Confusion

Fatigue and weakness often accompany diminished output from the left ventricle. Cardiac fatigue is different from general fatigue in that it usually is not present in the morning but appears and progresses as activity increases during the day.

In acute or severe left-sided failure, cardiac output may fall to levels that are insufficient for providing the brain with adequate oxygen, and there are indications of mental confusion and disturbed behavior. Confusion, impairment of memory, anxiety, restlessness, and insomnia are common in elderly persons with advanced heart failure, particularly in those with cerebral atherosclerosis. These symptoms may confuse the diagnosis of heart failure in older adults because of their myriad of other causes associated with aging.

Fluid Retention and Edema

Many of the manifestations of heart failure result from the increased capillary pressures (increased hydrostatic pressures) that develop in the peripheral circulation in people with right-sided heart failure and in the pulmonary circulation in people with left-sided heart failure. The increased capillary pressure reflects an overfilling of the vascular system because of increased sodium and water retention and venous congestion, referred to earlier as *backward* failure, resulting from impaired cardiac output.7,14

**Nocturia** is a nightly increase in urine output that occurs relatively early in the course of heart failure. It occurs because of the increased cardiac output, renal blood flow, and glomerular filtration rate that follow the increased blood return to the heart when the person is in a supine position. **Oliguria**, which is a decrease in urine output, is a late sign related to a severely reduced cardiac output and resultant renal failure.

Transudation of fluid into the pleural cavity (hydrothorax) or the peritoneal cavity (ascites) may occur in people with advanced heart failure. Because the pleural veins drain into both the systemic and pulmonary venous beds, hydrothorax is observed more commonly in persons with hypertension involving both venous systems.7,14 Pleural effusion occurs as the excess fluid in the lung interstitial spaces crosses the visceral pleura, which in turn overwhelms the capacity of the pulmonary lymphatic system. Ascites occurs in people with increased pressure in the hepatic veins and veins draining the peritoneum. It usually reflects right ventricular failure and long-standing elevation of systemic venous pressure in chronic heart failure.7,14

Cachexia and Malnutrition

Cardiac cachexia is a condition of malnutrition and tissue wasting that occurs in people with end-stage heart failure. A number of factors probably contribute to its development, including the fatigue and depression that interfere with food intake, congestion of the liver and gastrointestinal structures that impairs digestion and absorption and produces feelings of fullness, and the circulating toxins and mediators released from poorly perfused tissues that impair appetite and contribute to tissue wasting.

Cyanosis

Cyanosis is the bluish discoloration of the skin and mucous membranes caused by excess desaturated hemoglobin in the blood; it often is a late sign of heart failure. Cyanosis may be central, caused by arterial desaturation resulting from impaired pulmonary gas exchange, or peripheral, caused by venous desaturation resulting from extensive extraction of oxygen at the capillary level. Central cyanosis is caused by conditions that impair oxygenation of the arterial blood, such as pulmonary edema, left heart failure, or right-to-left cardiac flow.
shunting. Peripheral cyanosis is caused by conditions such as low-output failure that result in delivery of poorly oxygenated blood to the peripheral tissues, or by conditions such as peripheral vasoconstriction that cause excessive removal of oxygen from the blood. Central cyanosis is best monitored in the lips and mucous membranes because these areas are not subject to conditions, such as a cold environment, that cause peripheral cyanosis. People with right-sided or left-sided heart failure may develop cyanosis especially around the lips and in the peripheral parts of the extremities.

**Arrhythmias and Sudden Cardiac Death**

Both atrial and ventricular arrhythmias occur in people with heart failure. Atrial fibrillation is the most common arrhythmia. Clinical manifestations associated with atrial fibrillation are related to loss of atrial contraction, tachycardia, irregular heart rate, and symptoms related to a drop in blood pressure. There is also strong evidence that people with heart failure are at increased risk for sudden cardiac arrest; that is, unwitnessed death or death that occurs within 1 hour of the symptom onset. In people with ventricular dysfunction, sudden death is caused most commonly by ventricular tachycardia or ventricular fibrillation.

**Diagnosis and Treatment**

**Diagnosis**

Diagnostic methods in heart failure are directed toward establishing the cause of the disorder and determining the extent of the dysfunction. Medical guidelines for diagnosis and treatment are clearly described in the AHA guidelines for heart failure management. Because heart failure represents the failure of the heart as a pump and can occur in the course of a number of heart diseases or other systemic disorders, the diagnosis of heart failure often is based on signs and symptoms related to the failing heart itself, such as shortness of breath and fatigue. The functional classification of the New York Heart Association (NYHA) is one guide to classifying the extent of dysfunction.

The NYHA functional classification classifies dysfunction into four classes:

1. Class I—People who have known heart disease without symptoms during ordinary activity
2. Class II—People who have heart disease who have slight limitations but not extreme fatigue, palpitations, dyspnea, or angina pain during regular activity
3. Class III—People with heart disease who are comfortable at rest but ordinary activity does result in fatigue, palpitations, dyspnea, and angina pain
4. Class IV—People who have marked progressive cardiac disease and are not comfortable at rest or minimal activity

The methods used in the diagnosis of heart failure include risk factor assessment, history and physical examination, laboratory studies, electrocardiography, chest radiography, and echocardiography. The history should include information related to dyspnea, cough, nocturia, generalized fatigue, and other signs and symptoms of heart failure. A complete physical examination includes assessment of heart rate, heart sounds, blood pressure, jugular veins for venous congestion, lungs for signs of pulmonary congestion, and lower extremities for edema. Laboratory tests are used in the diagnosis of anemia and electrolyte imbalances, and to detect signs of chronic liver congestion. Measurements of BNP and NT-proBNP can be useful if the diagnosis of heart failure is uncertain and as risk stratification. The use of serial BNP or NT-proBNP levels has not yet been well established.

Echocardiography plays a key role in assessing right and left ventricular wall motion (normal, akinesis, or hypokinesis), wall thickness, ventricular chamber size, valve function, heart defects, ejection fraction, and pericardial disease. Electrocardiographic findings may indicate atrial or ventricular hypertrophy, underlying disorders of cardiac rhythm, or conduction abnormalities such as right or left bundle branch block. Radionuclide ventriculography and cardiac angiography are recommended if there is reason to suspect coronary artery disease as the underlying cause for heart failure. Chest x-rays provide information about the size and shape of the heart and pulmonary vasculature. The cardiac silhouette can be used to detect cardiac hypertrophy and dilatation. Chest x-rays can indicate the relative severity of the failure by revealing if pulmonary edema is predominantly vascular or interstitial, or has advanced to the alveolar and bronchial stages. Cardiac magnetic resonance imaging (CMRI) and cardiac computed tomography (CCT) are used to document ejection fraction, ventricular preload, and regional wall motion.

Invasive hemodynamic monitoring may be used for assessment in acute, life-threatening episodes of heart failure. These monitoring methods include central venous pressure (CVP), pulmonary artery pressure monitoring, thermodilution measurements of cardiac output, and intra-arterial measurements of blood pressure. CVP reflects the amount of blood returning to the heart. Measurements of CVP are best obtained by a catheter inserted into the right atrium through a peripheral vein, or by the right atrial port (opening) in a pulmonary artery catheter. This pressure is decreased in hypovolemia and increased in right heart failure. The changes that occur in CVP over time usually are more significant than the absolute numeric values obtained during a single reading.

Ventricular volume pressures are obtained by means of a flow-directed, balloon-tipped pulmonary artery catheter. This catheter is introduced through a peripheral or central vein and then advanced into the right atrium. The balloon is then inflated with air, enabling the catheter to float through the right ventricle into the pulmonary artery until it becomes wedged in a small pulmonary vessel (Fig. 34.7). With the balloon inflated, the catheter monitors pulmonary capillary pressures (also called pulmonary capillary wedge pressure [PCWP]), which is in direct communication with pressures from the left heart. The pulmonary capillary pressures provide a means of assessing the pumping ability of the left heart.
Intra-arterial blood pressure monitoring provides a means for continuous monitoring of blood pressure. It is used in people with acute heart failure when aggressive intravenous medication therapy or a mechanical assist device is required. Measurements are obtained through a small catheter inserted into a peripheral artery, usually the radial artery. The catheter is connected to a pressure transducer, and beat-by-beat measurements of blood pressure are recorded. The monitoring system displays the contour of the pressure waveform and the systolic, diastolic, and mean arterial pressures, along with the heart rate and rhythm.

**Remember** Mr. Brown from the unit opener case study? He was diagnosed with high blood pressure and hypercholesteremia. His subsequent cardiac catheterization revealed mild ischemic occlusion that did not meet the criteria for a cardiac stent or angioplasty. This result, along with his low ejection fraction of 40%, indicated that the supply of oxygen to his heart muscle was moderately impaired, reducing the force developed by the left ventricle. Therefore, he was diagnosed with ischemic cardiomyopathy and was classified as having Stage B (American Heart Association) and Class II (New York Heart Association) heart failure.

**Treatment**

The goals of treatment are determined by the rapidity of onset and severity of the heart failure. People with AHFS require urgent therapy directed at stabilizing and correcting the cause of the cardiac dysfunction. For people with chronic heart failure, the goals of treatment are directed toward relieving the symptoms, improving the quality of life, and reducing or eliminating risk factors (e.g., hypertension, diabetes, obesity) with a long-term goal of slowing, halting, or reversing the cardiac dysfunction.\(^1,2,14,17\)

Treatment measures for both acute and chronic heart failure include nonpharmacologic and pharmacologic approaches. Mechanical support devices, including the intra-aortic balloon pump (for acute failure) and the ventricular assist device (VAD), sustain life in people with severe heart failure. Heart transplantation remains the treatment of choice for many people with end-stage heart failure.

**Nonpharmacologic Methods.** Exercise intolerance is typical in people with chronic heart failure.\(^19\) Consequently, individualized exercise training is important to maximize muscle conditioning. People who are not accustomed to exercise and those with more severe heart failure are started at a lower intensity and shorter sessions than those who are mostly asymptomatic. Sodium and fluid restriction and weight management are important for all people with heart failure; the degree of sodium and fluid restriction is individualized to the severity of heart failure. Counseling, health teaching, and ongoing evaluation programs help people with heart failure to manage and cope with their treatment regimen.

**Pharmacologic Treatment.** Once heart failure is moderate to severe, pharmacologic in conjunction with nonpharmacologic management is important to prevent and treat acute heart failure and manage chronic heart failure. Evidence-based agents recommended for treatment and management include diuretics, ACE inhibitors or angiotensin II receptor blockers, β-adrenergic blockers, and digoxin.\(^1,2,14,17,20\) The choice of pharmacologic agents is based on symptomatology of the person.

**Diuretics** are among the most frequently prescribed medications for moderate to severe heart failure.\(^1,2,20\) They promote the excretion of fluid and help to sustain cardiac output and tissue perfusion by reducing preload and allowing the heart to operate at a more optimal part of the Frank-Starling curve. Thiazide and loop diuretics are used. In emergencies, such as acute pulmonary edema, loop diuretics such as furosemide can be administered intravenously. When given as a bolus infusion, intravenous furosemide acts within minutes to increase venous capacitance so that right ventricular output and pulmonary capillary pressures are decreased.

The **ACE inhibitors**, which prevent the conversion of angiotensin I to angiotensin II, have been used effectively in the treatment of chronic heart failure. The renin–angiotensin–aldosterone system is activated early in the course of heart failure and plays an important role in its progression. It results in an increase in angiotensin II, which causes vasoconstriction, unregulated ventricular remodeling, and increased aldosterone production with a subsequent increase in sodium and water retention by the kidneys. ACE inhibitors have been shown to limit these harmful complications. The angiotensin II receptor blockers appear to have similar but more limited beneficial effects. They have the advantage of not causing a cough, which is a troublesome side effect of the ACE inhibitors for
many people. Aldosterone has a number of deleterious effects in people with heart failure. Aldosterone receptor antagonists may be used in combination with other agents for people with moderately severe to severe heart failure.

β-Adrenergic receptor blocking drugs are used to decrease left ventricular dysfunction associated with activation of the sympathetic nervous system. Large clinical trials have shown that long-term therapy with β-adrenergic receptor blocking agents reduces morbidity and mortality in people with chronic heart failure. The mechanism of this benefit remains unclear, but it is likely that chronic elevations of catecholamines and sympathetic nervous system activity cause progressive myocardial damage, leading to a worsening of left ventricular function and a poorer prognosis in people with heart failure. Large, landmark clinical trials of people with stable NYHA class II and III heart failure have demonstrated significant reductions in the overall mortality rate with treatment with various β-adrenergic receptor blocking agents.21,22

Digitalis has been a recognized treatment for heart failure for over 200 years. The various forms of digitalis are called cardiac glycosides. They improve cardiac function by increasing the force and strength of ventricular contractions. By decreasing sinoatrial node activity and decreasing conduction through the atrioventricular node, they also slow the heart rate and increase diastolic filling time. Although not a diuretic, digitalis promotes urine output by improving cardiac output and renal blood flow. The role of digitalis in the treatment of heart failure has been studied in clinical trials over the past several decades. The results of these studies remain controversial and mixed; there seems to be a growing consensus that although it does not necessarily reduce mortality rates, digitalis can possibly prevent clinical deterioration and hospitalization.

Vasodilator drugs have not been extensively studied as a lone treatment for the management of heart failure but can be effective in symptom management. Agents such as isosorbide dinitrate and hydralazine may be added to other standard medications for patients with chronic heart failure. Vasodilators such as nitroglycerin, nitroprusside, and nesiritide (B-type NP) are used in AHFS to improve left heart performance by decreasing the preload (through vasodilation) or reducing the afterload (through arteriolar dilation), or both.23,24

Oxygen Therapy. Oxygen therapy increases the oxygen content of the blood and is most often used in people with acute episodes of heart failure. Continuous positive airway pressure (CPAP) is recommended to reduce the need for endotracheal intubation in patients with AHFS.25 Because CPAP increases intrathoracic pressure, it also has the potential for decreasing venous return and left ventricular preload, thereby improving the cardiac ejection fraction and stabilizing the hemodynamic status in persons with severe heart failure. Bilevel positive airway pressure (BiPAP), which is like CPAP but also delivers higher pressures during inspiration, is argued by some to be superior to CPAP in that it decreases the respiratory rate and heart rate and improves oxygenation more quickly or more substantially than CPAP.25

Cardiac Resynchronization and Implantable Cardioverter–Defibrillators. Some people with heart failure have abnormal intraventricular conduction that results in dysynchronous and ineffective contractions.26 Cardiac resynchronization therapy involves the placement of pacing leads into the right and left ventricles as a means of resynchronizing the contraction of the two ventricles. Cardiac resynchronization has been shown to improve ventricular function and blood pressure, improve quality of life, and reduce the risk of death.23

People with heart failure are at significant risk of sudden cardiac death from ventricular fibrillation or ventricular tachycardia. Implantation of a cardioverter–defibrillator is indicated in selected patients with heart failure to prevent sudden cardiac death.23 A cardioverter–defibrillator is a programmable implanted device that monitors the cardiac rhythm. It has the capacity to pace the heart and deliver electrical shocks to terminate lethal arrhythmias when needed.

Mechanical Support and Heart Transplantation. Refractory heart failure reflects deterioration in cardiac function that is unresponsive to medical or surgical interventions. With improved methods of treatment, more people are reaching a point where a cure is unachievable and death is imminent without mechanical support or heart transplantation.

Since the early 1960s, significant progress has been made in improving the efficacy of VADs, which are mechanical pumps used to support ventricular function. VADs are used to decrease the workload of the myocardium while maintaining cardiac output and systemic arterial pressure. This decreases the workload on the ventricle and allows it to rest and recover. In the past, VADs require an invasive open chest procedure for implantation but is not less invasive. They may be used in people who fail or have difficulty being weaned from cardiopulmonary bypass after cardiac surgery, those who develop cardiogenic shock after myocardial infarction, those with end-stage cardiomyopathy, and those who are awaiting cardiac transplantation. Earlier and more aggressive use of VADs as a bridge to transplantation and destination therapy (permanent support) has been shown to increase survival.23 VADs that allow the patient to be mobile and managed at home are sometimes used for long-term or permanent support for treatment of end-stage heart failure, rather than simply as a bridge to transplantation. VADs can be used to support the function of the left ventricle, right ventricle, or both.23

Heart transplantation is the preferred treatment for people with end-stage cardiac failure and otherwise good life expectancy.27 Despite the overall success of heart transplantation, donor availability remains a key problem, and only about 5000 procedures are completed each year with thousands being denied transplantation each year.

Other novel surgical therapies that are being explored include left ventricular remodeling. Left ventricular remodeling is a surgical procedure designed to restore the size and shape of the ventricle and is thought to be a viable surgical alternative to cardiac transplantation for people with severe left ventricular dysfunction.28
Heart failure occurs when the heart fails to pump sufficient blood to meet the metabolic needs of body tissues. The physiology of heart failure reflects the interplay between a decrease in cardiac output that accompanies impaired function of the failing heart and the compensatory mechanisms that preserve the cardiac reserve. Compensatory mechanisms include the Frank-Starling mechanism, sympathetic nervous system activation, the renin-angiotensin-aldosterone mechanism, NPs, the endothelins, and myocardial hypertrophy and remodeling. In the failing heart, early decreases in cardiac function may go unnoticed because these compensatory mechanisms maintain the cardiac output. Unfortunately, the mechanisms were not intended for long-term use, and in severe and prolonged heart failure, the compensatory mechanisms no longer are effective and instead contribute to the progression of heart failure.

Heart failure may be described in terms of systolic versus diastolic dysfunction and right ventricular versus left ventricular dysfunction. With systolic dysfunction, there is impaired ejection of blood from the heart during systole; with diastolic dysfunction, there is impaired filling of the heart during diastole. Right ventricular dysfunction is characterized by congestion in the peripheral circulation, and left ventricular dysfunction by congestion in the pulmonary circulation. Heart failure can present as a chronic condition characterized by decreased cardiac function or as an AHFS. The AHFS represents a gradual or rapid change in heart failure signs and symptoms, indicating need for urgent therapy. These symptoms are primarily the result of pulmonary congestion due to elevated left ventricular filling pressures with or without a low cardiac output.

The manifestations of heart failure include edema, nocturia, fatigue and impaired exercise tolerance, cyanosis, signs of increased sympathetic nervous system activity, and impaired gastrointestinal function and malnutrition. In right-sided failure, there is dependent edema of the lower parts of the body, engorgement of the liver, and ascites. In left-sided failure, pulmonary congestion with shortness of breath and chronic, nonproductive cough are common.

The diagnostic methods in heart failure are directed toward establishing the cause and extent of the disorder. Treatment is directed toward correcting the cause whenever possible, improving cardiac function, maintaining the fluid volume within a compensatory range, and developing an activity pattern consistent with individual limitations in cardiac reserve. Among the medications used in the treatment of heart failure are diuretics, ACE inhibitors and angiotensin receptor blocking agents, β-adrenergic receptor blockers, digoxin, and vasodilators. Mechanical support devices, including the VAD, sustain life in persons with severe heart failure. Heart transplantation remains the treatment of choice for many persons with end-stage heart failure.

**CIRCULATORY FAILURE (SHOCK)**

After completing this section of the chapter, you should be able to meet the following objectives:

- Compare the causes, pathophysiology, and chief characteristics of cardiogenic, hypovolemic, obstructive, and distributive shock.
- Describe the complications of shock as they relate to the lungs, kidneys, gastrointestinal tract, and blood clotting.
- State the rationale for treatment measures to correct and reverse shock.

Circulatory shock can be described as an acute failure of the circulatory system to supply the peripheral tissues and organs of the body with an adequate blood supply, resulting in cellular hypoxia. Most often hypotension and hypoperfusion are present, but shock may occur in the presence of normal vital signs. Shock is not a specific disease but a syndrome that can occur in the course of many life-threatening traumatic conditions or disease states. It can be caused by an alteration in cardiac function (cardiogenic shock), a decrease in blood volume (hypovolemic shock), excessive vasodilation with maldistribution of blood flow (distributive shock), or obstruction of blood flow through the circulatory system (obstructive shock). The main types of shock are summarized in Chart 34.1 and depicted in Figure 34.8.

Pathophysiology of Circulatory Shock

Circulatory failure results in hypoperfusion of organs and tissues, which in turn results in insufficient supply of oxygen and nutrients for cellular function. There are compensatory physiologic responses that eventually decompensate into various shock states if the condition is not properly treated in a timely manner. The most immediate of the compensatory mechanisms are the sympathetic and renin systems, which are designed to maintain cardiac output and blood pressure.

There are two types of adrenergic receptors for the sympathetic nervous system: α and β. The β receptors are further subdivided into β1 and β2 receptors. Stimulation of the α receptors causes vasoconstriction; stimulation of β1 receptors, an increase in heart rate and force of myocardial contraction; and of β2 receptors, vasodilation of the skeletal muscle beds and relaxation of the bronchioles. In shock, there is an increase in sympathetic outflow that results in increased epinephrine and norepinephrine release, and activation of both α and β receptors. Thus, increases in heart rate and vasoconstriction occur in most types of shock. There also is an increase in renin release, leading to an increase in angiotensin II, which augments vasoconstriction and leads to an aldosterone-mediated increase in sodium and water retention by the kidneys. In addition, there is local release of vasoconstrictors, including norepinephrine, angiotensin II, vasopressin, and endothelin, which contribute to arterial and venous vasoconstriction.

The compensatory mechanisms that the body recruits are not effective over the long term and become detrimental when the shock state is prolonged. The intense vasoconstriction causes a decrease in tissue perfusion and insufficient supply of oxygen. Cellular metabolism is impaired, vasoactive inflammatory mediators such as histamine are released, production of oxygen free radicals is increased, and excessive lactic acid and hydrogen ions result in intracellular acidity. Each of these factors promotes cellular dysfunction or death. If circulatory function is reestablished, whether the shock is irreversible or the patient will survive is determined largely at the cellular level.

Shock ultimately exerts its effect at the cellular level, with failure of the circulation to supply the cell with the oxygen and nutrients needed for production of ATP. The cell uses ATP for a number of purposes, including operation of the sodium–potassium membrane pump that moves sodium out
of the cell and potassium back into the cell. The cell uses two pathways to convert nutrients to energy. The first is the anaerobic (non-oxygen-dependent) glycolytic pathway, which is located in the cytoplasm. Glycolysis converts glucose to ATP and pyruvate. The second pathway is the aerobic (oxygen-dependent) pathway, called the citric acid cycle, which is located in the mitochondria. When oxygen is available, pyruvate from the glycolytic pathway moves into the mitochondria and enters the citric acid cycle, where it is transformed into ATP and the metabolic by-products carbon dioxide and water. When oxygen is lacking, pyruvate does not enter the citric acid cycle; instead, it is converted to lactic acid. The anaerobic pathway, although allowing energy production to continue in the absence of oxygen, is relatively inefficient and produces significantly less ATP than the aerobic pathway.

In severe shock, cellular metabolic processes are essentially anaerobic owing to the decreased availability of oxygen. Excess amounts of lactic acid accumulate in the cellular and the extracellular compartments, and limited amounts of ATP are produced. Without sufficient energy production, normal cell function cannot be maintained. The sodium–potassium membrane pump is impaired, resulting in excess sodium inside the cells and potassium loss from cells. The increase in intracellular sodium results in cellular edema and increased intracellular contents into the extracellular space. The destruction of the cell membrane activates the arachidonic acid cascade, release of inflammatory mediators, and production of oxygen free radicals that extend cellular damage.

The extent of the microvascular injury and organ dysfunction is primarily determined by the extent of the shock state and whether it is prolonged. Interventions are targeted at prevention and early intervention, when possible.

**Cardiogenic Shock**

Cardiogenic shock occurs when the heart fails to pump blood sufficiently to meet the body’s demands (see Fig. 34.8). Clinically, it is defined as decreased cardiac output, hypotension, hypoperfusion, and indications of tissue hypoxia, despite adequate intravascular volume. Cardiogenic shock may occur suddenly from a number of causes, including myocardial infarction, myocardial contusion, sustained arrhythmias, and cardiac surgery. Cardiogenic shock also may ensue as an end-stage condition of coronary artery disease or cardiomyopathy.

**Pathophysiology**

The most common cause of cardiogenic shock is myocardial infarction. Most people who die of cardiogenic shock have had extensive damage to the contracting muscle of the left ventricle because of a recent infarct or a combination of recent and old infarctions. Cardiogenic shock can occur with other types of shock because of inadequate coronary blood flow.

Regardless of cause, people with cardiogenic shock have a decrease in stroke volume and cardiac output, which results in insufficient perfusion to meet cellular demands for oxygen. The poor cardiac output is due to decreased myocardial contractility, increased afterload, and excessive preload. Mediators and neurotransmitters, including norepinephrine, produce an increase in systemic vascular resistance, which increases afterload and contributes to the deterioration of cardiac function. Preload, or the filling pressure of the heart, is increased as blood returning to the heart is added to blood that previously was not pumped forward, resulting in an increase in left ventricular end-systolic volume. Activation of the renin–angiotensin–aldosterone mechanism worsens both preload and afterload by producing an aldosterone-mediated increase in fluid retention and an angiotensin II–mediated increase in vasoconstriction. The increased resistance (i.e., afterload) to ejection of blood from the left ventricle, in combination with a decrease in myocardial contractility, results in an increase in end-systolic ventricular volume and preload, which further impairs the heart’s ability to pump effectively.

Eventually, coronary artery perfusion is impaired because of the increased preload and afterload, and cardiac function decreases because of poor myocardial oxygen supply. There is an increase in intracardiac pressures due to volume overload and ventricular wall tension in both diastole and systole. Excessive pressures decrease coronary artery perfusion during diastole, and increased wall tension decreases coronary artery perfusion during systole. If treatment is unsuccessful, cardiogenic shock may result in a systemic inflammatory response syndrome. This is evidenced by increased white blood cell count, increased temperature, and release of inflammatory markers such as CRP.

**Clinical Manifestations**

Signs and symptoms of cardiogenic shock include indications of hypoperfusion with hypotension, although a preshock state of hypoperfusion may occur with a normal blood pressure. The lips, nail beds, and skin may become cyanotic because
of stagnation of blood flow and increased extraction of oxygen from the hemoglobin as it passes through the capillary bed. Mean arterial and systolic blood pressures decrease due to poor stroke volume, and there is a narrow pulse pressure and near-normal diastolic blood pressure because of arterial vasoconstriction. Urine output decreases because of lower renal perfusion pressures and the increased release of aldosterone. Elevated preload is reflected in a rise in CVP and PCWP. Neurologic changes, such as alterations in cognition or consciousness, may occur because of low cardiac output and poor cerebral perfusion.

**Treatment**

Treatment of cardiogenic shock requires striking a precarious balance between improving cardiac output, reducing the workload and oxygen needs of the myocardium, and increasing coronary perfusion. Fluid volume must be regulated within a level that maintains the filling pressure and optimizes stroke volume in people not fluid overloaded. Pulmonary edema and arrhythmias should be monitored, corrected, or prevented to increase stroke volume and decrease the oxygen demands of the heart. Coronary artery perfusion is increased by promoting coronary artery vasodilation, increasing blood pressure, decreasing ventricular wall tension, and decreasing intracardiac pressures.

Pharmacologic treatment includes the use of vasodilators such as nitroprusside and nitroglycerin. Both nitroprusside and nitroglycerin cause coronary artery dilation, which increases myocardial oxygen delivery. Nitroprusside causes arterial and venous dilation, producing a decrease in venous return to the heart and a reduction in arterial resistance against which the left heart must pump. At lower doses, the main effects of nitroglycerin are on the venous vascular beds and coronary arteries. At high doses, it also dilates the arterial beds. Both medications may result in a decrease in diastolic arterial pressure that results in a lower systemic vascular resistance (afterload). The systolic arterial pressure is maintained by an increase in ventricular stroke volume, which is ejected against the lowered systemic vascular resistance. The improvement in heart function increases stroke volume and enables blood to be redistributed from the pulmonary vascular bed to the systemic circulation.

Positive inotropic agents are used to improve cardiac contractility. Both dobutamine and milrinone are effective medications in that they result in increased contractility and arterial vasodilation. Dobutamine is a synthetic agent consisting of two isomers, one of which is a potent β1-adrenergic receptor agonist and α1-adrenergic receptor antagonist and the other is a mild β2-adrenergic receptor agonist and α1-adrenergic receptor agonist. The combination tends to produce vasodilation and a positive inotropic action. Milrinone increases myocardial contractility by increasing the movement of Ca++ into myocardial cells during an action potential (see Fig. 34.1). The increase in stroke volume results in a decrease in end-systolic volume and a reduction in preload. With a decrease in preload pressures, coronary artery perfusion is improved during diastole. Thus, stroke volume and myocardial oxygen supply are improved with a minimal increase in myocardial oxygen demand. Catecholamines increase cardiac contractility but must be used with extreme caution because they also result in arterial constriction and increased heart rates, which worsen the imbalance between myocardial oxygen supply and demand.

The intra-aortic balloon pump, also referred to as counterpulsation, enhances coronary and systemic perfusion, yet decreases afterload and myocardial oxygen demands. The device, which pumps in synchrony with the heart, consists of a 10-inch-long balloon that is inserted through a catheter into the descending aorta (Fig. 34.9). The balloon is timed to inflate during ventricular diastole and deflate just before...
ventricular systole. Diastolic inflation creates a pressure wave in the ascending aorta that increases coronary artery blood flow and a less intense wave in the lower aorta that enhances organ perfusion. The abrupt balloon deflation at the onset of systole results in a displacement of blood volume that lowers the resistance to ejection of blood from the left ventricle. Thus, the heart’s pumping efficiency is increased, myocardial oxygen supply is increased, and myocardial oxygen consumption is decreased.

When cardiogenic shock is caused by myocardial infarction, several aggressive interventions can be used successfully. Fibrinolytic therapy, percutaneous coronary intervention, or CABG may be used to prevent or treat cardiogenic shock. Hypovolemic shock also can result from an internal hemorrhage or from third-space losses, when extracellular fluid is shifted from the vascular compartment to the interstitial space or compartment.

**Pathophysiology**

Hypovolemic shock, which has been the most widely studied type of shock, is often used as a prototype in discussions of the manifestations of shock. Figure 34.10 shows the effect of removing blood from the circulatory system during approximately 30 minutes. Approximately 10% of the total blood volume can be removed without changing cardiac output or arterial pressure. The average blood donor loses approximately 500 mL or 10% of their blood without experiencing adverse effects. As increasing amounts of blood (10% to 25%) are removed, the stroke volume falls but arterial pressure is maintained because of sympathetic-mediated increases in heart rate and vasoconstriction. Vasoconstriction results in an increased diastolic pressure and narrow pulse pressure. Blood pressure is the product of cardiac output and systemic vascular
resistance (blood pressure = cardiac output × systemic vascular resistance). An increase in systemic vascular resistance maintains mean arterial pressure for a short time despite decreased cardiac output. Cardiac output and tissue perfusion decrease before signs of hypotension appear. Cardiac output and arterial pressure fall to zero when approximately 30% to 40% of the total blood volume has been removed.3,29

**Compensatory Mechanisms.** Without compensatory mechanisms to maintain cardiac output and blood pressure, the loss of vascular volume would result in a rapid progression from the initial to the progressive and irreversible stages of shock. The most immediate of the compensatory mechanisms are the sympathetic-mediated responses designed to maintain cardiac output and blood pressure (Fig. 34.10). Within seconds after the onset of hemorrhage or the loss of blood volume, tachycardia, increased cardiac contractility, vasoconstriction, and other signs of sympathetic and adrenal medullary activity appear. The sympathetic vasoconstrictor response also mobilizes blood that has been stored in the venous side of the circulation as a means of increasing venous return to the heart. There is considerable capacity for blood storage in the large veins of the abdomen, and approximately 350 mL of blood that can be mobilized in shock is stored in the liver.3 Sympathetic stimulation does not initially cause constriction of the cerebral and coronary vessels, and blood flow to the heart and brain is maintained at essentially normal levels as long as the mean arterial pressure remains above 70 mm Hg.3

Compensatory mechanisms designed to restore blood volume include absorption of fluid from the interstitial spaces, conservation of sodium and water by the kidneys, and thirst. Extracellular fluid is distributed between the interstitial spaces and the vascular compartment. When there is a loss of vascular volume, capillary pressures decrease and water is drawn into the vascular compartment from the interstitial spaces. The maintenance of vascular volume is further enhanced by renal mechanisms that conserve fluid. A decrease in renal blood flow and glomerular filtration rate results in activation of the renin–angiotensin–aldosterone mechanism, which produces an increase in sodium reabsorption by the kidneys. The decrease in blood volume also stimulates centers in the hypothalamus that regulate ADH release and thirst. ADH, also known as vasopressin, constricts the peripheral arteries and veins and greatly increases water retention by the kidneys. Although the mechanism of ADH is more sensitive to changes in serum osmolality, a decrease of 10% to 15% in blood volume serves as a strong stimulus for thirst.3,29

During the early stages of hypovolemic shock, vasoconstriction decreases the size of the vascular compartment and increases systemic vascular resistance. This response usually is all that is needed when the injury is slight and blood loss is minimal. As hypovolemic shock progresses, vasoconstriction of the blood vessels that supply the skin, skeletal muscles, kidneys, and abdominal organs becomes more severe, with a further decrease in blood flow and conversion to anaerobic metabolism resulting in cellular injury.

**Clinical Manifestations**

The signs and symptoms of hypovolemic shock depend on its severity and are closely related to low peripheral blood flow and excessive sympathetic stimulation. They include thirst, increased heart rate, cool and clammy skin, decreased arterial blood pressure, decreased urine output, and changes in mentation. Laboratory tests of hemoglobin and hematocrit provide information regarding the severity of blood loss or hemococoncentration due to dehydration. Serum lactate and arterial pH provide information about the severity of acidosis due to anaerobic metabolism. Metabolic acidosis revealed by arterial blood gas measurement is the gold standard diagnostic test.29,33 Acute, fatal hemorrhagic shock is characterized by metabolic acidosis, coagulopathy, and hypothermia, followed by circulatory failure.33

An increase in heart rate is an early sign of hypovolemic shock, as the body tries to maintain cardiac output despite the decrease in stroke volume. As shock progresses, the pulse becomes weak and thready, indicating vasoconstriction and reduced filling of the vascular compartment. Thirst is an early symptom in hypovolemic shock. Although the underlying cause is not fully understood, it probably is related to decreased blood volume and increased serum osmolality.

Arterial blood pressure is decreased in moderate to severe shock. However, controversy exists over the value of blood pressure measurements in the early diagnosis and management of shock. This is because compensatory mechanisms tend to preserve blood pressure until shock is relatively far advanced. Furthermore, a normal arterial pressure does not ensure adequate perfusion and oxygenation of vital organs at the cellular level. This does not imply that blood pressure should not be closely monitored in people at risk for development of shock, but it does indicate the need for other assessment measures.

As shock progresses, the respirations become rapid and deep, to compensate for the increased production of acid and decreased availability of oxygen. Decreased intravascular volume results in decreased venous return to the heart and a decreased CVP. When shock becomes severe, the peripheral veins may collapse. Sympathetic stimulation leads to intense vasoconstriction of the skin vessels, which results in cool and mottled skin. In hemorrhagic shock, the loss of red blood cells results in pallor of the skin and mucous membranes.

Urine output decreases very quickly in hypovolemic shock. Compensatory mechanisms decrease renal blood flow as a means of diverting blood flow to the heart and brain. Oliguria of 20 mL/hour or less indicates inadequate renal perfusion. Continuous measurement of urine output is essential for assessing the circulatory and volume status of the person in shock.

Restlessness, agitation, and apprehension are common in early shock because of increased sympathetic outflow and increased levels of epinephrine. As the shock progresses and blood flow to the brain decreases, restlessness is replaced by altered arousal and mentation. Loss of consciousness and coma may occur if the person does not receive or respond to treatment.
Treatment
The duration and amount of fluid loss is directly related to mortality. Therefore, the treatment of hypovolemic shock is directed toward correcting or controlling the underlying cause and improving tissue perfusion. Ongoing loss of blood must be corrected. Oxygen is administered to increase oxygen delivery to the tissues. Medications usually are administered intravenously. Frequent measurements of heart rate and cardiac rhythm, blood pressure, and urine output are used to assess the severity of circulatory compromise and to monitor treatment.

In hypovolemic shock, the goal of treatment is to restore vascular volume. This can be accomplished through intravenous administration of fluids and blood. The crystalloids (e.g., isotonic saline and Ringer lactate) are readily available and effective, at least temporarily. Plasma volume expanders (e.g., pentastarch and colloidal albumin) have a high molecular weight, do not necessitate blood typing, and remain in the vascular space for longer periods than crystalloids such as dextrose and saline. The use of crystalloids versus colloids has not been studied in large clinical trials. Therefore, the use of one versus the other to decrease morbidity has not been established. Blood or blood products (packed or frozen red cells) may be detrimental. These agents are given only when volume deficits have been corrected yet hypotension persists.

Distributive Shock
Distributive or vasodilatory shock is characterized by loss of blood vessel tone, enlargement of the vascular compartment, and displacement of the vascular volume away from the heart and central circulation. In distributive shock, the capacity of the vascular compartment expands to the extent that a normal volume of blood does not fill the circulatory system (see Fig. 34.8). Therefore, this type of shock is also referred to as normovolemic shock. Two main causes result in the loss of vascular tone: a decrease in the sympathetic control of vasomotor tone or the release of excessive vasodilator substances. It can also occur as a complication of vessel damage resulting from prolonged and severe hypotension due to hemorrhage, known as irreversible or late-phase hemorrhagic shock.

There are three shock states that share the basic circulatory pattern of distributive shock: neurogenic shock, anaphylactic shock, and septic shock.

Neurogenic Shock
Neurogenic shock is caused by decreased sympathetic control of blood vessel tone due to a defect in the vasomotor center in the brain stem or the sympathetic outflow to the blood vessels. The term spinal shock describes the neurogenic shock that occurs in persons with spinal cord injury. Output from the vasomotor center can be interrupted by brain injury, the depressant action of drugs, general anesthesia, hypoxia, or lack of glucose (e.g., insulin reaction). Painting due to emotional causes is a transient form of impaired sympathetic outflow. Many general anesthetic agents can cause a neurogenic shock–like reaction, especially during induction, because of interference with sympathetic nervous system function. Spinal anesthesia or spinal cord injury above the midthoracic region can interrupt the transmission of outflow from the vasomotor center. In contrast to other shock states due to the loss of blood volume or impaired cardiac function, the heart rate in neurogenic shock often is slower than normal, and the skin is dry and warm. This type of distributive shock is rare and usually transitory.

Anaphylactic Shock
Anaphylaxis is a clinical syndrome that represents the most severe systemic allergic reaction. Anaphylactic shock results from an immunologically mediated reaction in which vasodilator substances such as histamine are released into the blood. These substances cause vasodilation of arterioles and venules along with a marked increase in capillary permeability. The vascular response in anaphylaxis is often accompanied by life-threatening laryngeal edema and bronchospasm, circulatory collapse, contraction of gastrointestinal and uterine smooth muscle, and urticaria (hives) or angioedema.

Etiology. Among the most frequent causes of anaphylactic shock are reactions to medications, such as penicillin; foods, such as nuts and shellfish; and insect venoms. The most common cause is stings from insects of the order Hymenoptera (i.e., bees, wasps, and fire ants). Latex allergy causes life-threatening anaphylaxis in a growing segment of the population. Health care workers and others who are exposed to latex are developing latex sensitivities that range from mild urticaria, contact dermatitis, and mild respiratory distress to anaphylactic shock.

The onset and severity of anaphylaxis depend on the sensitivity of the person and the rate and quantity of antigen exposure.

Clinical Manifestations. Signs and symptoms associated with impending anaphylactic shock include the following:

- Abdominal cramps
- Apprehension
- Warm or burning sensation of the skin
- Itching
- Urticaria (i.e., hives)
- Coughing
- Choking
- Wheezing
- Chest tightness
- Difficulty in breathing
After blood begins to pool peripherally, there is a precipitous drop in blood pressure and the pulse becomes so weak that it is difficult to detect. Life-threatening airway obstruction may ensue as a result of laryngeal angioedema or bronchial spasm. Anaphylactic shock often develops suddenly; death can occur within minutes unless appropriate medical intervention is promptly instituted.

**Treatment.** Treatment includes immediate discontinuation of the inciting agent or institution of measures to decrease its absorption (e.g., application of ice to the site of an insect bite); close monitoring of cardiovascular and respiratory function; and maintenance of respiratory gas exchange, cardiac output, and tissue perfusion. Epinephrine is given in an anaphylactic reaction because it constricts blood vessels and relaxes the smooth muscle in the bronchioles, thus restoring cardiac and respiratory function. Other treatment measures include the administration of oxygen, antihistamine drugs, and corticosteroids. The person should be placed in a supine position. This is extremely important because venous return can be severely compromised in the sitting position. This in turn produces a pulseless mechanical contraction of the heart and predisposes to arrhythmias. In several cases, death has occurred immediately after assuming the sitting position.

**Prevention.** The prevention of anaphylactic shock is preferable to treatment. Once a person has been sensitized to an antigen, the risk of repeated anaphylactic reactions with subsequent exposure is high. All health care providers should question people regarding previous drug reactions and inform people as to the name of the medication they are to receive before it is administered or prescribed. People with known hypersensitivities should wear Medic Alert jewelry and carry an identification card to alert medical personnel if they become unconscious or unable to relate this information. People who are at risk for anaphylaxis should be provided with emergency medications (e.g., epinephrine autoinjector) and instructed in procedures to follow in case they are inadvertently exposed to the offending antigen.

**Sepsis and Septic Shock**

Sepsis, which is the most common type of vasodilatory shock, is associated with severe infection and the systemic response to infection (Fig. 34.11). Sepsis is currently defined as suspected or proven infection, plus a systemic inflammatory response syndrome (e.g., fever, tachycardia, tachypnea, elevated white blood cell count, altered mental state, and hyperglycemia in the absence of diabetes). Severe sepsis is defined as sepsis with organ dysfunction (e.g., hypotension, hypoxemia, oliguria, metabolic acidosis, thrombocytopenia, or obtundation). Septic shock is defined as severe sepsis with hypotension, despite fluid resuscitation. It is estimated that sepsis occurs in 500 people each day in the United States. The growing incidence has been attributed to enhanced awareness of the diagnosis, increased number of resistant organisms, growing number of immunocompromised and older adults, and greater use of invasive procedures. With early intervention and advances in treatment methods, the mortality rate has decreased. However, the number of deaths has increased because of the increased prevalence.

**Pathophysiology.** The pathogenesis of sepsis involves a complex process of cellular activation resulting in the release of proinflammatory mediators such as cytokines; recruitment of neutrophils and monocytes; involvement of neuroendocrine reflexes; and activation of complement, coagulation, and fibrinolytic systems. Initiation of the response begins with activation of the innate immune system by pattern-recognition receptors (e.g., toll-like receptors [TLRs]) that interact with...
specific molecules present on microorganisms. Binding of TLRs to epitopes on microorganisms stimulates transcription and release of a number of proinflammatory and anti-inflammatory mediators. Two of these mediators, TNF-α and interleukin-1, are involved in leukocyte adhesion, local inflammation, neutrophil activation, suppression of erythropoiesis, generation of fever, tachycardia, lactic acidosis, ventilation-perfusion abnormalities, and other signs of sepsis as discussed earlier. Although activated neutrophils kill microorganisms, they also injure the endothelium by releasing mediators that increase vascular permeability. In addition, activated endothelial cells release nitric oxide, a potent vasodilator that acts as a key mediator of septic shock.

Another important aspect of sepsis is an alteration of the procoagulation–anticoagulation balance with an increase in procoagulation factors and a decrease in anticoagulation factors. Lipopolysaccharide on the surface of microorganisms stimulates endothelial cells lining blood vessels to increase their production of tissue factor, thus activating coagulation. Fibrinogen is then converted to fibrin, leading to the formation of microvascular thrombi that further amplify tissue injury. In addition, sepsis lowers levels of protein C, protein S, antithrombin III, and tissue factor pathway inhibitor, substances that modulate and inhibit coagulation. Lipopolysaccharide and TNF-α also decrease the synthesis of thrombomodulin and endothelial protein C receptor, impairing activation of protein C, and they increase the synthesis of plasminogen activator inhibitor-1, impairing fibrinolysis.

Clinical Manifestations. Sepsis and septic shock typically manifests with hypotension and warm, flushed skin. Whereas other forms of shock (i.e., cardiogenic, hypovolemic, and obstructive) are characterized by a compensatory increase in systemic vascular resistance, septic shock often presents with a decrease in systemic vascular resistance. There is hypovolemia due to arterial and venous dilatation, plus leakage of plasma into the interstitial spaces. Abrupt changes in cognition or behavior are due to reduced cerebral blood flow and may be early indications of septic shock. Regardless of the underlying cause, fever and increased leukocytes are present. An elevated serum lactate or metabolic acidosis indicates anaerobic metabolism due to tissue hypoxia or cellular dysfunction and altered cellular metabolism. Tissue hypoxia produces continued production and activation of inflammatory mediators, resulting in further increases in vascular permeability, impaired vascular regulation, and altered hemostasis.

Treatment. The treatment of sepsis and septic shock focuses on control of the causative agent and support of the circulation. Early use of antibiotics is essential, followed by anti-biotic therapy specific to the infectious agent. However, antibiotics do not treat the inflammatory response to the infection. Thus, the cardiovascular status of the person must be supported to increase oxygen delivery to the cells and prevent further cellular injury. Swift and aggressive fluid administration is needed to compensate for third spacing. Equally aggressive use of vasoconstrictive agents, such as vasopressin, norepinephrine, and phenylephrine, is needed to counteract the vasodilation caused by inflammatory mediators. A positive inotrope, such as dobutamine or milrinone, may be used to augment cardiac output. Ongoing assessment of oxygen, CVP, central or mixed venous oxygen saturation, mean arterial pressure, and urinary output and laboratory measurements of blood cultures, serum lactate, base deficit, and pH are used to evaluate the progression of sepsis and adequacy of treatment.

Among the more recent advances in the treatment of sepsis are the use of intensive insulin therapy for hyperglycemia and the administration of recombinant human activated protein C. It has been demonstrated that intensive insulin therapy that maintained blood glucose levels at 80 to 110 mg/dL (4.4 to 6.1 mmol/L) resulted in lower mortality and morbidity than did conventional therapy that maintained blood glucose levels at 180 to 200 mg/dL (10 to 11 mmol/L). Hyperglycemia is potentially harmful because it acts as a procoagulant, induces apoptosis, impairs neutrophil function, increases the risk of infection, and impairs wound healing. Recombinant human activated protein C (drotrecogin alfa), a naturally occurring anticoagulant factor that acts by inactivating coagulation factors Va and VIII, is the first agent that has demonstrated effectiveness in the treatment of sepsis. In addition to its anticoagulant actions, activated protein C has direct anti-inflammatory properties, including blocking the production of cytokines by monocytes and blocking cell adhesion. Activated protein C also has antiapoptotic actions that may contribute to its effectiveness. The use of corticosteroids, once considered a mainstay in the treatment of sepsis, remains controversial. There is little to no evidence that the use of corticosteroids can improve patient outcomes. It should only be considered when fluid resuscitation and vasoactive support have not shown any improvement in the status of the person with sepsis.

Obstructive Shock

The term obstructive shock describes circulatory shock that results from mechanical obstruction of the flow of blood through the central circulation (great veins, heart, or lungs; see Fig. 34.8). Obstructive shock may be caused by a number of conditions, including dissecting aortic aneurysm, cardiac tamponade, pneumothorax, atrial myxoma, and evisceration of abdominal contents into the thoracic cavity because of a ruptured hemidiaphragm. The most frequent cause of obstructive shock is pulmonary embolism.

The primary physiologic result of obstructive shock is elevated right heart pressure due to impaired right ventricular function. Pressures are increased despite impaired venous return to the heart. Signs of right heart failure occur, including elevation of CVP and jugular venous distention. Treatment modalities focus on correcting the cause of the disorder,
Complications of Shock

Many body systems are destroyed by shock. Five major complications of severe shock are the following:

1. Pulmonary injury
2. Acute renal failure
3. Gastrointestinal ulceration
4. Disseminated intravascular coagulation (DIC)
5. Multiple organ dysfunction syndrome (MODS)

These complications of shock are serious and often fatal.

Acute Lung Injury/Acute Respiratory Distress Syndrome

Acute lung injury/acute respiratory distress syndrome (ALI/ARDS) is a potentially lethal form of pulmonary injury that may be either the cause or result of shock. ARDS is a more severe aspect of ALI and is differentiated primarily for early intervention, prevention, and research purposes.

ARDS is marked by the rapid onset of profound dyspnea that usually occurs 12 to 48 hours after the initiating event. The respiratory rate and effort of breathing increase. Arterial blood gas analysis establishes the presence of profound hypoxemia that is refractory to supplemental oxygen. The hypoxemia results from impaired matching of ventilation and perfusion and from the greatly reduced diffusion of blood gases across the thickened alveolar membranes.

The exact cause of ALI/ARDS is unknown. Neutrophils are thought to play a key role in its pathogenesis. A cytokine-mediated activation and accumulation of neutrophils in the pulmonary vasculature and subsequent endothelial injury are thought to cause leaking of fluid and plasma proteins into the interstitium and alveolar spaces. The fluid leakage causes atelectasis, impairs gas exchange, and makes the lung stiff and more difficult to inflate. Abnormalities in the production, composition, and function of surfactant may contribute to alveolar collapse and gas exchange abnormalities. Inappropriate vasodilation and vasoconstriction worsen the ventilation and perfusion mismatch.

Interventions for ALI/ARDS focus on increasing the oxygen concentration in the inspired air and supporting ventilation mechanically to optimize gas exchange while avoiding oxygen toxicity and preventing further lung injury. Although the delivery of high levels of oxygen using high-pressure mechanical ventilatory support and positive end-expiratory pressure may correct the hypoxemia, the mortality rate varies from 35% to 40%. The major causes are the initiating incident and multiple organ system failure.

Acute Renal Failure

The renal tubules are particularly vulnerable to ischemia, and acute renal failure is an important factor in mortality due to severe shock. Most cases of acute renal failure are due to impaired renal perfusion or direct injury to the kidneys. The degree of renal damage is related to the severity and duration of shock. The normal kidney is able to tolerate severe ischemia for 15 to 20 minutes. The renal dysfunction most frequently seen after severe shock is acute tubular necrosis. Acute tubular necrosis usually is reversible, although return to normal renal function may require weeks or months. Continuous monitoring of urinary output during shock provides a means of assessing renal blood flow. Frequent monitoring of serum creatinine and blood urea nitrogen levels also provides valuable information regarding renal status.

Mediators implicated in septic shock are powerful vasoconstrictors capable of activating the sympathetic nervous system and causing intravascular clotting. They have been shown to trigger all the separate physiologic mechanisms that contribute to the onset of acute renal failure.

Gastrointestinal Complications

The gastrointestinal tract is particularly vulnerable to ischemia because of the changes in distribution of blood flow to its mucosal surface. In shock, there is widespread constriction of blood vessels that supply the gastrointestinal tract, causing a redistribution of blood flow and a severe decrease in mucosal perfusion. People may experience loss of appetite, nausea, or vomiting. Superficial mucosal lesions of the stomach and duodenum can develop within hours of severe trauma, sepsis, or burns. Bowel obstruction or bleeding may occur after the decrease in perfusion in shock. Hemorrhage usually has its onset within 2 to 10 days after the original insult and often begins without warning. Poor perfusion in the gastrointestinal tract has been credited with allowing intestinal bacteria to enter the bloodstream, thereby contributing to the development of sepsis and shock.

Histamine type 2 receptor antagonists, proton pump inhibitors, or sucralfate may be given prophylactically to prevent gastrointestinal ulcerations caused by shock. Nasogastric tubes, when attached to intermittent suction, also help to diminish the accumulation of hydrogen ions in the stomach.

Disseminated Intravascular Coagulation

Disseminated intravascular coagulation (DIC) is characterized by widespread activation of the coagulation system with resultant formation of fibrin clots and thrombotic occlusion of small and midsized vessels. The systemic formation of fibrin results from increased generation of thrombin, the simultaneous suppression of physiologic anticoagulation mechanisms, and the delayed removal of fibrin as a consequence of impaired fibrinolysis. Clinically overt DIC is reported to occur in as much as 1 in every 1000 people in the United States. As with other systemic inflammatory responses, the derangement...
of coagulation and fibrinolysis is thought to be mediated by inflammatory mediators and cytokines.

The contribution of DIC to morbidity and mortality in sepsis depends on the underlying clinical condition and the intensity of the coagulation disorder. Depletion of the platelets and coagulation factors increases the risk of bleeding. Deposition of fibrin in the vasculature of organs contributes to ischemic damage and organ failure. However, it remains uncertain whether DIC was a predictor of unfavorable outcome or merely a marker of the seriousness of the underlying condition causing the DIC.

The management of sepsis-induced DIC focuses on treatment of the underlying disorder and measures to interrupt the coagulation process. Anticoagulation therapy and administration of blood products may be used.

**Multiple Organ Dysfunction Syndrome**

Multiple organ dysfunction syndrome (MODS) represents the presence of altered organ function in an acutely ill person such that homeostasis cannot be maintained without intervention. As the name implies, MODS commonly affects multiple organ systems, including the kidneys, lungs, liver, brain, and heart. MODS is a particularly life-threatening complication of shock, especially septic shock. It has been reported as the most frequent cause of death in the noncoronary intensive care unit. Mortality rates vary from 30% to 100%, depending on the number of organs involved. Mortality rates increase with an increased number of organs failing. A high mortality rate is associated with failure of the brain, liver, kidneys, and lungs. The pathogenesis of MODS is not clearly understood, and current management therefore is primarily supportive. Major risk factors for the development of MODS are severe trauma, sepsis, prolonged periods of hypotension, hepatic dysfunction, infarcted bowel, advanced age, and alcohol abuse.

Interventions for multiple organ failure are focused on support of the affected organs.

---

**HEART FAILURE IN CHILDREN AND OLDER ADULTS**

After completing this section of the chapter, you should be able to meet the following objectives:

- Describe the causes of heart failure in infants and children.
- Explain how the aging process affects cardiac function and predisposes to ventricular dysfunction.
- Identify how the signs and symptoms of heart failure may differ between younger and older adults.

**Heart Failure in Infants and Children**

As in adults, heart failure in infants and children results from the inability of the heart to maintain the cardiac output required to sustain metabolic demands. The etiology of heart failure, however, is very different between children and
adults. Structural (congenital) heart defects are the most common cause of heart failure in children. Surgical correction of congenital heart defects may cause heart failure as a result of intraoperative manipulation of the heart and resection of heart tissue, with subsequent alterations in pressure, flow, and resistance relations. Usually, the heart failure that results is acute and resolves after the effects of the surgical procedure have subsided. Another cause of heart failure in children is cardiomyopathy related to a genetic or inherited disorder, infectious disease, drugs, toxins, and Kawasaki disease.52 Chart 34.2 lists some of the more common causes of heart failure in children, which include the following:

- Inflammatory heart disorders (e.g., myocarditis, rheumatic fever, bacterial endocarditis, Kawasaki disease)
- Cardiomyopathy
- Congenital heart defects

**Clinical Manifestations**

Many of the signs and symptoms of heart failure in infants and children are similar to those in adults. In children, overt symptoms of heart failure occur late in the disease process.53 Breathlessness, tachypnea, and tachycardia felt as palpitations are the most common symptoms.52 Other symptoms include fatigue, effort intolerance, cough, anorexia, and abdominal pain. A subtle sign of cardiorespiratory distress in infants and children is a change in disposition or responsiveness, including irritability or lethargy. Sympathetic stimulation produces peripheral vasoconstriction and diaphoresis. Decreased renal blood flow often results in a decrease in urine output despite adequate fluid intake.

When right ventricular function is impaired, systemic venous congestion develops. Hepatomegaly due to liver congestion often is one of the first signs of systemic venous congestion in infants and children. However, dependent edema or ascites rarely is seen unless the CVP is extremely high. Because of their short, fat necks, jugular venous distention is difficult to detect in infants. It is not a reliable sign until the child is of school age or older. A third heart sound, or gallop rhythm, is a common finding in infants and children with heart failure. It results from rapid filling of a noncompliant ventricle. However, it is difficult to distinguish at high heart rates.

Most commonly, children develop interstitial pulmonary edema rather than alveolar pulmonary edema. This reduces lung compliance and increases the work of breathing, causing tachypnea and increased respiratory effort. Older children display use of accessory muscles (i.e., scapular and sternocleidomastoid). Head bobbing and nasal flaring may be observed in infants. Signs of respiratory distress often are the first and most noticeable indication of heart failure in infants and young children. Pulmonary congestion may be mistaken for bronchiolitis or lower respiratory tract infection. The infant or young child with respiratory distress often grunts with expiration. This grunting effort (essentially, exhaling against a closed glottis) is an instinctive effort to increase end-expiratory pressures and prevent collapse of small airways and the development of atelectasis. Respiratory crackles are uncommon in infants and usually suggest development of a respiratory tract infection. Wheezes may be heard, particularly if there is a large left-to-right shunt.

Infants with heart failure often show increased tachypnea, fatigue, and diaphoresis during feeding.52 Weight gain is slow owing to high energy requirements and low calorie intake. Diaphoresis occurs (because of increased sympathetic tone) particularly over the head and neck. They may have repeated

**Chart 34.2**

**CAUSES OF HEART FAILURE IN CHILDREN**

**Newborn Period**
- Congenital heart defects
  - Severe left ventricular outflow disorders
  - Hypoplastic left heart
  - Critical aortic stenosis or coarctation of the aorta
- Large arteriovenous shunts
- Ventricular septal defects
- Patent ductus arteriosus
- Transposition of the great vessels
- Heart muscle dysfunction (secondary)
  - Asphyxia
  - Sepsis
  - Hypoglycemia
- Hematologic disorders (e.g., anemia)

**Infants 1 to 6 Months**
- Congenital heart disease
  - Large arteriovenous shunts (ventricular septal defect)
- Heart muscle dysfunction
- Myocarditis
- Cardiomyopathy
- Pulmonary abnormalities
  - Bronchopulmonary dysplasia
  - Persistent pulmonary hypertension

**Toddlers, Children, and Adolescents**
- Acquired heart disease
  - Cardiomyopathy
  - Viral myocarditis
  - Rheumatic fever
  - Endocarditis
  - Systemic disease
  - Sepsis
  - Kawasaki disease
  - Renal disease
  - Sickle cell disease
- Congenital heart defects
  - Nonsurgically treated disorders
  - Surgically treated disorders
- Heart muscle dysfunction
- Myocarditis
- Cardiomyopathy
- Pulmonary abnormalities
  - Bronchopulmonary dysplasia
  - Persistent pulmonary hypertension
- Congenital heart defects
  - Nonsurgically treated disorders
  - Surgically treated disorders
- Acquired heart disease
  - Cardiomyopathy
  - Viral myocarditis
  - Rheumatic fever
  - Endocarditis
  - Systemic disease
  - Sepsis
  - Kawasaki disease
  - Renal disease
  - Sickle cell disease
- Congenital heart defects
  - Nonsurgically treated disorders
  - Surgically treated disorders

lower respiratory tract infections. Peripheral perfusion usually is poor, with cool extremities; tachycardia is common (resting heart rate >150 beats/minute); and the respiratory rate is increased (resting rate >50 breaths/minute).52

**Diagnosis and Treatment**

Diagnosis of heart failure in infants and children is based on symptomatology, chest radiographic films, electrocardiographic findings, echocardiographic techniques to assess cardiac structures and ventricular function (i.e., end-systolic and end-diastolic diameters), arterial blood gases to determine intracardiac shunting and ventilation–perfusion inequalities, and other laboratory studies to determine anemia and electrolyte imbalances.

Treatment of heart failure in infants and children includes measures aimed at improving cardiac function and eliminating excess intravascular fluid. Oxygen delivery must be supported and oxygen demands controlled or minimized. Whenever possible, the cause of the disorder is corrected (e.g., medical treatment of sepsis and anemia, surgical correction of congenital heart defects). With congenital anomalies that are amenable to surgery, medical treatment often is needed for a time before surgery and usually is continued in the immediate postoperative period. For some children, only medical management can be provided.

Medical management of heart failure in infants and children is similar to that in the adult, although it is tailored to the special developmental needs of the child. Inotropic agents such as digitalis often are used to increase cardiac contractility. Diuretics may be given to reduce preload and vasodilating medications used to manipulate the afterload. Medication doses must be carefully tailored to control for the child’s weight and conditions such as reduced renal function. Daily weighing and accurate measurement of intake and output are imperative during acute episodes of failure. Most children feel better in the semiupright position. An infant seat is useful for infants with chronic heart failure. Activity restrictions usually are designed to allow children to be as active as possible within the limitations of their heart disease. Infants with heart failure often have problems feeding. Small, frequent feedings usually are more successful than larger, less frequent feedings. Severely ill infants may lack sufficient strength to suck and may need to be tube fed.

The treatment of heart failure in children should be designed to allow optimal physical and psychosocial development. It requires the full involvement of the parents, who often are the primary care providers. Therefore, parent education and support are essential.

**Heart Failure in Older Adults**

Heart failure is largely a disease of aging. It is one of the most common causes of disability in older adults and is the most frequent hospital admission and discharge diagnosis for older adults (those older than 65 years) in the United States and Canada.54 Among the factors that have contributed to the increased numbers of older adults with heart failure are the improved therapies for ischemic and hypertensive heart disease.53 Thus, people who would have died from acute myocardial disease 20 years ago are now surviving but with residual left ventricular dysfunction. Advances in treatment of other diseases have also contributed indirectly to the rising prevalence of heart failure in the older population.

Coronary heart disease, hypertension, arrhythmias, and valvular heart disease (particularly aortic stenosis and mitral regurgitation) are common causes of heart failure in older adults.56 In contrast to the etiology in middle-aged people with heart failure, factors other than systolic failure contribute to heart failure in older adults. Preserved left ventricular function may be seen in 40% to 80% of older adults with heart failure.57 Aging is associated with impaired left ventricular filling due to changes in myocardial relaxation and compliance. These alterations lead to a shift in the left ventricular pressure–volume relationship, such that small increases in left ventricular volume lead to greater increases in left ventricular diastolic pressure. This increase in diastolic pressure further compromises left ventricular filling and leads to increases in left atrial, pulmonary venous, and pulmonary capillary pressures, and thus predisposes to pulmonary congestion and heart failure.58 Although diastolic heart failure accounts for less than 10% of heart failure cases in people younger than 60 years of age, it accounts for greater than 50% of cases after age 75 years.58

There are a number of changes associated with aging that contribute to the development of heart failure in older adults.55,56,59 First, reduced responsiveness to β-adrenergic stimulation limits the heart’s capacity to maximally increase heart rate and contractility. A second major effect of aging is increased vascular stiffness, which leads to a progressive increase in systolic blood pressure with advancing age, which in turn contributes to the development of left ventricular hypertrophy and altered diastolic filling. Third, in addition to increased vascular stiffness, the heart itself becomes stiffer and less compliant with age. The changes in diastolic stiffness result in important alterations in diastolic filling and atrial function. A reduction in ventricular filling not only affects cardiac output but produces an elevation in diastolic pressure that is transmitted back to the left atrium, where it stretches the muscle wall and predisposes to atrial ectopic beats and atrial fibrillation. The fourth major effect of cardiovascular aging is altered myocardial metabolism at the level of the mitochondria. Although older mitochondria may be able to generate sufficient ATP to meet the normal energy needs of the heart, they may not be able to respond under stress.

**Clinical Manifestations**

The manifestations of heart failure in older adults often are masked by other disease conditions.2 Nocturia and nocturnal incontinence is an early symptom but may be caused by other conditions such as prostatic hypertrophy. Lower extremity edema may reflect venous insufficiency. Impaired perfusion
of the gastrointestinal tract is a common cause of anorexia and profound loss of lean body mass. Loss of lean body mass may be masked by edema. Exertional dyspnea, orthopnea, and impaired exercise tolerance are cardinal symptoms of heart failure in both younger and older adults with heart failure. However, with increasing age, which is often accompanied by a more sedentary lifestyle, exertional dyspnea becomes less prominent. Instead of dyspnea, the prominent sign may be restlessness. Chart 34.3 summarizes the clinical manifestations of heart failure in older adults.

Physical signs of heart failure, such as elevated jugular venous pressure, hepatic congestion, $S_3$ gallop, and pulmonary crackles, occur less commonly in older adults, in part because of the increased incidence of diastolic failure, in which signs of right-sided heart failure are late manifestations and a third heart sound is typically absent. Instead, behavioral changes and altered cognition such as short-term memory loss and impaired problem solving are more common. Depression is common in older adults with heart failure and shares the symptoms of sleep disturbances, cognitive changes, and fatigue.

Older adults also maintain a precarious balance between the managed symptom state and acute symptom exacerbation. During the managed symptom state, they are relatively symptom-free while adhering to their treatment regimen. Acute symptom exacerbation, often requiring emergency medical treatment, can be precipitated by seemingly minor conditions such as poor adherence to sodium restriction, infection, or stress. Failure to promptly seek medical care is a common cause of progressive acceleration of symptoms.

**Diagnosis and Treatment**

The diagnosis of heart failure in older adults is based on the history, physical examination, chest radiograph, and electrocardiographic findings. However, the presenting symptoms of heart failure often are difficult to evaluate. Symptoms of dyspnea on exertion are often interpreted as a sign of “getting older” or attributed to deconditioning from other diseases. Ankle edema is not unusual in older adults because of decreased skin turgor and the tendency of older adults to be more sedentary with the legs in a dependent position.

Treatment of heart failure in older adults involves many of the same methods as in younger people, with medication dose adaptations to reduce age-related adverse and toxic events. ACE inhibitors may be particularly beneficial to preserve cognitive and functional capacities. Activities may be restricted to a level that is commensurate with the cardiac reserve. Seldom is bed rest recommended or advised. Bed rest causes rapid deconditioning of skeletal muscles and increases the risk of complications such as orthostatic hypotension and thromboemboli. Instead, carefully prescribed exercise programs can help to maintain activity tolerance. Even walking around a room usually is preferable to continuous bed rest. Sodium restriction usually is indicated. Since older adults have the highest hospital readmission rates, education is extremely important and it is imperative to involve the family members and caregivers in their management and treatment. It is also important to have a multidisciplinary approach to their care with frequent contact since they will have other comorbid conditions and can deteriorate rapidly.

The mechanisms of heart failure in children and older adults are similar to those in adults. However, the causes and manifestations may differ because of age. In children, heart failure is seen most commonly during infancy and immediately after heart surgery. It can be caused by congenital and acquired heart defects and is characterized by fatigue, effort intolerance, cough, anorexia, abdominal pain, and impaired growth. Treatment of heart failure in children includes correction of the underlying cause whenever possible. For congenital anomalies that are amenable to surgery, medical treatment often is needed for a time before surgery and usually is continued in the immediate postoperative period. For many children, only medical management can be provided.

In older adults, age-related changes in cardiovascular functioning contribute to heart failure but are not in themselves sufficient to cause heart failure. The clinical manifestations of heart failure often are different and superimposed on other disease conditions. Therefore, heart failure often is more difficult to diagnose in older adults than in younger people. Because older adults are more susceptible to adverse and toxic medication reactions, medication doses need to be adapted and more closely monitored.
1. A 75-year-old male with long-standing hypertension and angina due to coronary heart disease presents with ankle edema, nocturia, increased shortness of breath with activity, and a chronic nonproductive cough. He has a past history of smoking two packs per day and is an ex-alcoholic. His blood pressure is 170/80 and his heart rate is 100. Electrocardiography and chest radiography indicate the presence of left ventricular hypertrophy.

A. Relate the presence of uncontrolled hypertension and coronary artery disease to the development of heart failure in this man.

B. Explain the significance of left ventricular hypertrophy in terms of both a compensatory mechanism and as a pathologic mechanism in the progression of heart failure.

C. Explain the management and treatment for this diagnosis.

2. A 21-year-old man is admitted to the emergency department with excessive blood loss after an automobile injury. He is alert and anxious, his skin is cool and moist, his heart rate is 135, and his blood pressure is 100/85. He is receiving intravenous fluids, which were started at the scene of the accident by an emergency medical technician. He has been typed and cross-matched for blood transfusions and a urinary catheter has been inserted to monitor his urinary output. His urinary output has been less than 10 mL since admission and his blood pressure has dropped to 85/70. Efforts to control his bleeding have been unsuccessful and he is being prepared for emergency surgery.

A. Use information regarding the compensatory mechanisms in circulatory shock to explain this man’s presenting symptoms, including urinary output.

B. The treatment of hypovolemic shock is usually directed at maintaining the circulatory volume through fluid resuscitation rather than maintaining the blood pressure through the use of vasoactive medications. Explain.

Ms. French presents to the emergency department with shortness of breath (SOB) and a nonproductive cough. Her vital signs are as follows: temperature, 99.3°F; heart rate, 132 beats/minute; respiratory rate, 20 breaths/minute; blood pressure, 110/64 mm Hg; and pulse oximetry, 94% on room air. Physical examination reveals decreased breath sounds on the right side, sharp chest pain with inspiration, and soreness in her right calf. Ms. French has taken oral contraceptives daily for 6 years but takes no other medications. She smokes 1 pack of cigarettes per day. There is no significant family history. An electrocardiogram (ECG) shows sinus tachycardia. Chest x-ray is not significant. A computed tomography (CT) scan reveals a small thrombus in the right main pulmonary artery. Arterial blood gases (ABGs) at time of presentation are as follows: pH, 7.47; PaCO₂, 31 mm Hg; PaO₂, 86 mm Hg; SaO₂, 93%; and HCO₃⁻, 24 mEq/L. These values indicate she is in respiratory alkalosis. Serum levels are within normal limits, except d-dimer, 0.7 mg/L (normal: <0.5 mg/L), and troponin I, 0.4 ng/mL (normal: <0.0 to 0.2 ng/mL). Ms. French is diagnosed with a pulmonary embolism, and immediate treatment with heparin is instituted.

There is more information on Ms. French in Chapter 35 and Chapter 37.
The primary function of the respiratory system, which consists of the airways and lungs, is gas exchange. Oxygen from the air is transferred to the blood, and carbon dioxide from the blood is eliminated into the atmosphere. In addition to gas exchange, the lungs serve as a host defense by providing a barrier between the external environment and the inside of the body. Finally, the lung is also a metabolic organ that synthesizes and metabolizes different compounds.

This chapter focuses on the structural organization of the respiratory system, exchange of gases between the atmosphere and the lungs, exchange of gases in the lungs and its transport in the blood, and control of breathing.

After completing this section of the chapter, you should be able to meet the following objectives:

- State the difference between the conducting and the respiratory airways.
- Trace the movement of air through the airways, beginning in the nose and oropharynx and moving into the respiratory tissues of the lung.
- Differentiate the function of the bronchial and pulmonary circulations that supply the lungs.
The respiratory system consists of the air passages (two lungs) and the blood vessels that supply them. It also consists of the structures that provide a ventilator mechanism, that is, the rib cage and the respiratory muscles, which include the diaphragm—the principal respiratory muscle.

The lungs are soft, spongy, cone-shaped organs located side by side in the chest cavity (Fig. 35.1). They are separated from each other by the mediastinum (i.e., the space between the lungs) and its contents—the heart, blood vessels, lymph nodes, nerve fibers, thymus gland, and esophagus. The upper part of the lung, which lies against the top of the thoracic cavity, is called the apex, and the lower part, which lies against the diaphragm, is called the base. The lungs are divided into lobes, three in the right lung and two in the left.

Functionally, the respiratory system can be divided into two parts: the conducting airways, through which air moves as it passes between the atmosphere and the lungs, and the respiratory tissues of the lungs, where gas exchange takes place.

**KEY POINTS**

**CONDUCTING AND RESPIRATORY AIRWAYS**

- Respiration requires ventilation, or movement of gases into and out of the lungs; perfusion, or movement of blood through the lungs; and diffusion of gases between the lungs and the blood.
- Ventilation depends on the conducting airways, including the nasopharynx and oropharynx, larynx, and tracheobronchial tree, which move air into and out of the lungs but do not participate in gas exchange.
- Gas exchange takes place in the respiratory airways of the lungs, where gases diffuse across the alveolar–capillary membrane as they are exchanged between the air in the lungs and the blood that flows through the pulmonary capillaries.

**FIGURE 35.1** The respiratory system. (A) Upper respiratory structures and the structures of the thorax, (B) alveoli, and (C) a horizontal cross section of the lungs. (From Smeltzer C., Bare B. G., Hinkle J. L., et al. (2009). *Brunner & Suddarth’s textbook of medical-surgical nursing* (12th ed., p. 488). Philadelphia, PA: Lippincott Williams & Wilkins.)
Conducting Airways

The conducting airways consist of the nasal passages, mouth and pharynx, larynx, trachea, bronchi, and bronchioles (see Fig. 35.1). Besides functioning as a conduit for airflow, the conducting airways serve to “condition” the inspired air. The air we breathe is warmed, filtered, and moistened as it moves through these structures. Heat is transferred to the air from the blood flowing through the walls of the respiratory passages. The mucociliary blanket removes foreign materials, and water from the mucous membranes is used to moisten the air.

A combination of cartilage, elastic and collagen fibers, and smooth muscle provides the airways with the rigidity and flexibility needed to maintain airway patency and ensure an uninterrupted supply of air. Most of the conducting airways are lined with ciliated pseudostratified columnar epithelium, containing a mosaic of mucus-secreting glands, ciliated cells with hairlike projections, and serous glands that secrete a watery fluid containing antibacterial enzymes (Fig. 35.2). The epithelial layer gradually becomes thinner as it moves from the pseudostratified epithelium of the bronchi to cuboidal epithelium of the bronchioles and then to squamous epithelium of the alveoli.

The mucus produced by the epithelial cells in the conducting airways forms a layer, called the mucociliary blanket. This layer protects the respiratory system by entrapping dust, bacteria, and other foreign particles that enter the airways. The cilia, which are in constant motion, move the mucociliary blanket with its entrapped particles in an escalator-like fashion toward the oropharynx. At this point, the mucociliary blanket is expectorated or swallowed. The function of cilia in clearing the lower airways is optimal at normal oxygen levels. Function is impaired when oxygen levels are higher or lower than normal. Drying conditions, such as breathing heated but unhumidified indoor air during the winter months, also impair function. Cigarette smoking slows down or paralyzes the motility of the cilia. This slowing allows the residue from tobacco smoke, dust, and other particles to accumulate in the lungs, decreasing the efficiency of this pulmonary defense system. These changes are thought to contribute to the development of chronic bronchitis and emphysema.

Water contained in the mucous membranes of the upper airways and the tracheobronchial tree keeps the conducting airways moist. The capacity of the air to contain moisture without condensation increases as the temperature rises. Thus, the air in the alveoli, which is maintained at body temperature, usually contains considerably more moisture than the atmosphere-temperature air that we breathe. The difference between the moisture contained in the air we breathe and that found in the alveoli is drawn from the moist surface of the mucous membranes that line the conducting airways. This is a source of insensible water loss. When a person has a fever, the water vapor in the lungs increases, causing more water to be lost from the respiratory mucosa. Also, fever usually is accompanied by an increase in respiratory rate so that more air needing to be moistened passes through the airways. As a result, respiratory secretions thicken, preventing free movement of the cilia and impairing the protective function of the mucociliary defense system. This is particularly true in people whose fluid intake is inadequate and/or who have dehydration due to another pathological cause.

Nasopharyngeal Airways

The mouth serves as an alternative airway when the nasal passages are plugged or when there is a need for the exchange of large amounts of air (e.g., during exercise). The oropharynx extends posteriorly from the soft palate to the epiglottis. The oropharynx is the only opening between the nose, mouth, and lungs. Both swallowed food on its way to the esophagus and air on its way to the larynx pass through it. Obstruction of the oropharynx leads to immediate cessation of ventilation. Neural control of the tongue and pharyngeal muscles may be impaired in coma and other neurologic disorders. In these conditions, the tongue falls

**FIGURE 35.2** Airway wall structure: bronchus, bronchiole, and alveolus. The bronchial wall contains pseudostratified epithelium, smooth muscle cells, mucus glands, connective tissue, and cartilage. In smaller bronchioles, a simple epithelium is found, cartilage is absent, and the wall is thinner. The alveolar wall is designed for gas exchange, rather than structural support. (From Porth C. M. (2011). Essentials of pathophysiology (3rd ed., p. 515). Philadelphia, PA: Lippincott Williams & Wilkins.)
back into the pharynx and obstructs the airway, particularly if the person is lying on his or her back. Swelling of the pharyngeal structures caused by injury, infection, or severe allergic reaction or the presence of a foreign body also predisposes a person to airway obstruction.

**Larynx**

The larynx connects the oropharynx with the trachea. It is located between the upper airways and the lungs. The walls of the larynx are supported by firm cartilaginous structures that prevent collapse during inspiration. The functions of the larynx can be divided into two categories: those associated with speech and those associated with protecting the lungs from substances other than air.

The cavity of the larynx is divided into two pairs of shelf-like folds stretching from front to back with an opening in the midline (Fig. 35.3). The upper pair of folds, called the **vestibular folds**, has a protective function. The lower pair of folds, called the **vocal folds**, produces the vibrations required for making vocal sounds. The vocal folds and the elongated opening between them are called the **glottis**. A complex set of muscles controls the opening and closing of the glottis. The **epiglottis**, which is located above the larynx, is a large, leaf-shaped piece of cartilage that is covered with epithelium. When only air is flowing through the larynx, the inlet of the larynx is open and the free edges of the epiglottis point upward. During swallowing, the larynx is pulled superiorly and the free edges of the epiglottis move downward to cover the larynx, thus routing liquids and foods into the esophagus.

In addition to opening and closing the glottis for speech, the vocal folds of the larynx can perform a sphincter function, closing off the airways. When confronted with substances other than air, the laryngeal muscles contract and close off the airway. At the same time, the cough reflex is initiated as a means of removing a foreign substance from the airway. If the swallowing mechanism is partially or totally paralyzed, food and fluids can enter the airways instead of the esophagus when a person attempts to swallow. These substances are not easily removed. When they are pulled into the lungs, they can cause a serious inflammatory condition called **aspiration pneumonia**.

**Tracheobronchial Tree**

The tracheobronchial tree, which consists of the trachea, bronchi, and bronchioles, can be viewed as a system of branching tubes flowing through the lobes of the lungs. There are approximately 23 levels of branching, beginning with the conducting airways and ending with the respiratory airways, where gas exchange takes place (see Fig. 35.4).

The trachea, or windpipe, is a continuous tube that connects the larynx and the major bronchi of the lungs. The walls of the trachea are supported by horseshoe- or C-shaped rings of hyaline cartilage, which prevent it from collapsing when the pressure in the thorax becomes negative (Fig. 35.5). The open part of the C ring, which abuts the esophagus, is connected by smooth muscle. Since this portion of the trachea is not rigid, the esophagus can expand anteriorly as swallowed food passes through it.

The trachea extends to the superior border of the fifth thoracic vertebra, where it divides to form the right and left main or primary bronchi. Between the main bronchi is a keel-like ridge, called the **carina** (Fig. 35.6). The mucosa of the carina is highly sensitive. For example, violent coughing is initiated when a foreign object (e.g., whole grape or large piece of hot dog or even the tip of the suction catheter) makes contact with it. The structure of the primary bronchi is similar to the trachea in that these airways are lined with a mucosal surface and supported by cartilaginous rings. Each primary bronchus, accompanied by the pulmonary arteries, veins, and lymph vessels, enters the lung through a slit called the **hilum**.

---

**FIGURE 35.3**  
(A) Coronal section showing the position of the epiglottis, the vestibular folds (false vocal cords), vocal folds (true vocal cords), and glottis. (B) Vocal cords viewed from above with glottis closed and (C) with glottis open.
On entering the lungs, each primary bronchus divides into secondary or lobular bronchi that supply each of the lobes of the lung—three in the right lung and two in the left (see Fig. 35.6). The right middle lobe bronchus is of relatively small diameter and length and sometimes bends sharply near its bifurcation. It is surrounded by a collar of lymph nodes that drain the middle and the lower lobe and is particularly subject to obstruction. The secondary bronchi, in turn, divide to form the segmental bronchi, which supply the bronchopulmonary segments of the lung. The trachea is the zero generation, the two main stem bronchi are the first generation, and as the airways get smaller and smaller, their generation number is identified (Fig. 35.7).

There are 10 segments on the right lung and 9 on the left. These segments are identified according to their location in the lung (e.g., the apical segment of the right upper lobe) and are the smallest named units in the lung. Lung disorders such as atelectasis and pneumonia often are localized to a particular bronchopulmonary segment. The structure of the secondary and segmental bronchi is similar, for the most part, to that of the primary bronchi. However, irregular plates of hyaline cartilage that completely surround the lumina of the bronchi replace the C-shaped cartilage rings. In addition, there are two layers of smooth muscle spiraling in opposite directions (Fig. 35.8).
Chapter 35  Structure and Function of the Respiratory System

Figure 35.6 (A) Anterior view of respiratory structures, including the lobes of the lung, the larynx, trachea, and the main bronchi on the left and the main pulmonary artery and vein on the right. (B) The carina is located at the bifurcation of the right and left mainstem bronchi.

Figure 35.7 Idealization of the human airways. The first 16 generations (Z) make up the conducting airways, and generations 17 to 23 make up the respiratory airways. Throughout childhood, the airways increase in diameter and length, and the number and size of the alveoli increase until adolescence, when respiratory development matures to that of an adult. (From West J. B. (2008) Respiratory physiology: The essentials (8th ed., p. 6). Philadelphia, PA: Lippincott Williams & Wilkins.)

Figure 35.8 Lobule of the lung, showing the bronchial smooth muscle fibers, pulmonary blood vessels, and lymphatics.
The segmental bronchi continue to branch, forming smaller bronchi, until they become the terminal bronchioles, the smallest of the conducting airways. As these bronchi branch and become smaller, their wall structure changes. The cartilage gradually decreases and there is an increase in smooth muscle and elastic tissue (with respect to the thickness of the wall). By the time the bronchioles are reached, there is no cartilage present and their walls are composed mainly of smooth muscle and elastic fibers. Bronchospasm, or contraction of these muscles, causes narrowing of the bronchioles and impairs airflow. The elastic fibers, which radiate from the outer layer of the bronchial wall and connect with elastic fibers arising from other parts of the bronchial tree, exert tension on the bronchial walls. By pulling uniformly in all directions, the elastic fibers help maintain airway patency.

Lungs and Respiratory Airways

The lungs are the functional structures of the respiratory system. In addition to their gas exchange function, they inactivate vasoactive substances such as bradykinin, they convert angiotensin I to angiotensin II, and they serve as a reservoir for blood storage.

Lobules

The gas exchange function of the lung takes place in the lobules of the lungs, which are the smallest functional units of the lungs. A branch of a terminal bronchiole, an arteriole, the pulmonary capillaries, and a venule supply each lobule (see Fig. 35.8).

Gas exchange takes place in the terminal respiratory bronchioles and the alveolar ducts and sacs. Blood enters the lobules through a pulmonary artery and exits through a pulmonary vein. Lymphatic structures surround the lobule and aid in the removal of plasma proteins and other particles from the interstitial spaces.

Unlike the larger bronchi, the respiratory bronchioles are lined with simple epithelium rather than ciliated pseudostratified epithelium (see Fig. 35.2). The respiratory bronchioles also lack the cartilaginous support of the larger airways. Instead, they are attached to the elastic spongielike tissue that contains the alveolar air spaces.

Alveoli

The alveoli are the terminal air spaces of the respiratory tract and the actual sites of gas exchange between the air and the blood. Each alveolus is a small outpouching of respiratory bronchioles, alveolar ducts, and alveolar sacs (see Fig. 35.8). The alveolar sacs are cup-shaped, thin-walled structures that are separated from each other by thin alveolar septa. A single network of capillaries occupies most of the septa, so blood is exposed to air on both sides. There are approximately 300 million alveoli in the adult lung, with a total surface area of approximately 50 to 100 m².1 Unlike the bronchioles, which are tubes with their own separate walls, the alveoli are interconnecting spaces that have no separate walls. As a result of this arrangement, there is a continual mixing of air in the alveolar structures. Small holes in the alveolar walls, the pores of Kohn, also contribute to the mixing of air.

The alveolar epithelium is composed of two types of cells: type I and type II alveolar cells (Fig. 35.9). The alveoli also contain brush cells and macrophages. The brush cells, which are few in number, are thought to act as receptors that monitor the air quality of the lungs. The macrophages, which are present in both the alveolar lumen and the septum of the alveoli, function to remove offending material from the lung.

Type I Alveolar Cells. The type I alveolar cells, also known as type I pneumocytes, are extremely thin squamous cells with a thin cytoplasm and flattened nucleus that occupy about 95% of the surface area of the alveoli. They are joined to one another and to other cells by occluding junctions. These junctions form an effective barrier between the air and the components of the alveolar wall. Type I alveolar cells are not capable of cell division.

Type II Alveolar Cells. The type II alveolar cells, also called type II pneumocytes, are small cuboidal cells located at the corners of the alveoli. Type II cells are as numerous as type I cells, but because of their different shape, they cover only about 5% of the alveolar surface area. The type II cells synthesize pulmonary surfactant, a substance that decreases the surface tension in the alveoli and allows for greater ease of lung inflation. They are also the progenitor cells for type I cells. After lung injury, they proliferate and restore both type I and type II alveolar cells.

Pulmonary surfactant is a complex mixture of phospholipids, neutral lipids, and proteins that is synthesized in the type II alveolar cells. Type II alveolar cells are rich in mitochondria and are metabolically active. Their apical cytoplasm contains stacks of parallel membrane sheets or lamellae, called the lamellar bodies. All of the components of surfactant are synthesized by the alveolar type II cells and stored as preformed units in the lamellar bodies. Secretion of surfactant occurs by exocytosis. The major route of clearance of surfactant within the lung is through reuptake by the type II cells. After reuptake, the phospholipids are either recycled or degraded and reused in the synthesis of new phospholipids.

The surfactant molecules produced by the type II alveolar cells reduce the surface tension at the air–epithelium interface and modulate the immune functions of the lung. There are four types of surfactant, each with a different molecular structure: surfactant apoproteins A (SP-A), B (SP-B), C (SP-C), and D (SP-D). SP-B and SP-C reduce the surface tension at the air–epithelium interface and increase lung compliance and ease of lung inflation. SP-B is particularly important to the generation of the surface-reducing film that makes lung...
expansion possible. For example, SP-B–deficiency disorders are often a result of single-gene disorders that cause acute and chronic respiratory dysfunction.2 SP-C is necessary for decreasing surface tension and stopping end-expiratory alveolar collapse.3 SP-A and SP-D do not reduce surface tension but contribute to host defenses that protect against pathogens that have entered the lung. They are members of the collectin protein family that function as a part of the innate immune system. Collectively, they opsonize pathogens, including bacteria and viruses, to facilitate phagocytosis by macrophages. They also regulate the production of inflammatory mediators. SP-A and SP-D are directly bactericidal, meaning they can kill bacteria in the absence of immune system effector cells. SP-D can be used to predict problems with acute lung injury (ALI) and acute respiratory distress syndrome (ARDS). Both of these conditions can best be predicted by using a combination of biomarkers (SP-D, neutrophil chemotactic factor, and interleukin-8) and clinical predictors (Acute Physiology and Chronic Health Evaluation III [APACHE III]). Therefore, it is most significant to measure SP-D in people experiencing chest trauma.4

Alveolar Macrophages. The macrophages are present in both the connective tissue of the septum and in the air spaces of the alveolus. They are responsible for the removal of offending substances from the alveoli. In the air spaces, they scavenge the surface to remove inhaled particulate matter, such as dust and pollen. Some macrophages pass up the bronchial tree in the mucus and are disposed of by swallowing or coughing when they reach the pharynx. Others enter the septic connective tissue, where, filled with phagocytosed materials, they remain for life. Thus, at autopsy, urban dwellers, as well as smokers, usually show many alveolar macrophages filled with carbon and other polluting particles from the environment. The alveolar macrophages also phagocytose insoluble infectious agents such as Mycobacterium tuberculosis. The activated macrophages then aggregate to form a fibrin-encapsulated granuloma, called a tubercle, to contain the infection. The tubercle bacillus can remain dormant in this stage or be reactivated years later, when the person’s immunologic tolerance wanes as the result of old age or immunosuppressive disease or therapy.

Pulmonary Vasculature and Lymphatic Supply

Pulmonary and Bronchial Circulations

The lungs are provided with a dual blood supply, the pulmonary and bronchial circulations. The pulmonary circulation arises from the pulmonary artery and provides for the gas exchange function of the lungs (see Fig. 35.8). Deoxygenated blood leaves the right heart through the pulmonary artery. The pulmonary artery divides into a left pulmonary artery that enters the left lung and a right pulmonary artery that enters the right lung. Return of oxygenated blood to the heart occurs by way of the pulmonary veins, which empty into
the left atrium. This is the only part of the circulation where arteries carry deoxygenated blood and veins carry oxygenated blood.

The bronchial circulation distributes blood to the conducting airways and the supporting structures of the lung. The bronchial circulation also has a secondary function of warming and humidifying incoming air as it moves through the conducting airways. The bronchial arteries arise from the thoracic aorta and enter the lungs with the major bronchi. They divide and subdivide along with the bronchi as they move out into the lung, supplying them and other lung structures with oxygen. The blood from the capillaries in the bronchial circulation drains into the bronchial veins, with the blood from the larger bronchial veins emptying into the vena cava. Blood from the smaller bronchial veins empties into the pulmonary veins. Because the bronchial circulation does not participate in gas exchange, this blood is deoxygenated. As a result, it dilutes the oxygenated blood returning to the left side of the heart through the pulmonary veins.

The bronchial blood vessels are the only ones that can undergo angiogenesis (formation of new vessels) and develop collateral circulation when vessels in the pulmonary circulation are obstructed, as in pulmonary embolism. The development of new blood vessels helps to keep lung tissue alive until the pulmonary circulation can be restored.

Lymphatic Circulation

The lungs are also supplied with lymphatic drainage that parallels their dual blood supply. One set of lymph vessels, the superficial vessels, drains the surface of the lung and travels in the connective tissue of the visceral pleura. A second set of the vessels, the deep lymphatic vessels, follows the pulmonary arteries, pulmonary veins, and bronchial tree down to the level of the respiratory bronchioles (see Fig. 35.8). Both of these systems have numerous interconnections, and both form networks that drain into the hilar lymph nodes at the base of each lung. Particulate matter entering the lung is partly removed through these channels, as are the plasma proteins that have escaped from the pulmonary capillaries. The latter function is particularly important in keeping the lungs dry and in preventing the accumulation of fluid in the pleural cavity.

Innervation

The sympathetic and parasympathetic divisions of the autonomic nervous system innervate the lung. It is parasympathetic stimulation, through the vagus nerve, that is responsible for the slightly constricted smooth muscle tone in the normal resting lung. There is no voluntary motor innervation of the lung, nor are there pain fibers. Pain fibers are found only in the pleura.

Stimulation of the parasympathetic nervous system leads to airway constriction and increased glandular secretion. Parasympathetic innervation of the lung arises from the vagal nuclei in the medulla. Preganglionic fibers from the vagal nuclei descend in the vagus nerve to ganglia adjacent to the airways and blood vessels of the lung. Postganglionic fibers from the ganglia then complete the network that innervates smooth muscle, blood vessels, and epithelial cells, including the goblet and submucosal glands. Both the preganglionic and postganglionic fibers contain excitatory (cholinergic) motor neurons that respond to acetylcholine. Parasympathetic innervation is greater in the large airways and diminishes toward the smaller airways.

Stimulation of the sympathetic nervous system causes airway relaxation, blood vessel constriction, and inhibition of glandular secretion. Sympathetic innervation arises from the cell bodies in paravertebral sympathetic ganglia. Neurotransmitters of the sympathetic nervous system include the catecholamines norepinephrine and epinephrine.

Pleura

A thin, transparent, double-layered serous membrane, called the pleura, lines the thoracic cavity and encases the lungs (see Fig. 35.10). The outer parietal layer lines the pulmonary cavities and adheres to the thoracic wall, the mediastinum, and the diaphragm. The inner visceral pleura closely covers the lung and is adherent to all its surfaces. It is continuous with the parietal pleura at the hilum of the lung, where the major bronchus and pulmonary vessels enter and leave the lung. A thin film of serous fluid separates the two pleural layers, allowing the two layers to glide over each other and yet hold together. In this way there is no separation between the lungs and the chest wall, which would potentially allow for infectious processes to build up and negatively impact chest wall expansion. The pleural cavity is a potential space in which serous fluid or inflammatory exudate can accumulate. The term pleural effusion is used to describe an abnormal collection of fluid or exudate in the pleural cavity.

IN SUMMARY

The respiratory system consists of the air passages and the lungs, where gas exchange takes place. Functionally, the air passages of the respiratory system can be divided into two parts: the conducting airways, through which air moves as it passes into and out of the lungs, and the respiratory tissues, where gas exchange actually takes place. The conducting airways include the nasal passages, mouth and nasopharynx, larynx, and tracheobronchial tree. Air is
warmed, filtered, and humidified as it passes through these structures.

The lungs are the functional structures of the respiratory system. In addition to their gas exchange function, they inactivate vasoactive substances such as bradykinin; they convert angiotensin I to angiotensin II; and they serve as a reservoir for blood. The lobules, which are the functional units of the lung, consist of the respiratory bronchioles, alveoli, and pulmonary capillaries. It is here that gas exchange takes place. Oxygen from the alveoli diffuses across the alveolar–capillary membrane into the blood, and carbon dioxide from the blood diffuses into the alveoli. There are two types of alveolar cells: type I and type II. Type I cells, which provide the gas exchange function of the lung, are extremely thin squamous cells lining most of the surface of the alveoli. Type II cells, which produce surfactant and serve as progenitor cells for type I cells, are small cuboidal cells. There are four types of surfactant protein (SP): SP-A, SP-B, SP-C, and SP-D. SP-B and SP-C provide the critical surface tension–lowering properties necessary for ease of lung inflation. SP-A and SP-D modulate the immune response to foreign pathogens and participate in local inflammatory responses.

The lungs are provided with a dual blood supply: the pulmonary circulation provides for the gas exchange function of the lungs and the bronchial circulation distributes blood to the conducting airways and supporting structures of the lung. The lungs are also supplied by a dual system of lymphatic vessels: a superficial system in the visceral pleura and a deep system that supplies deeper pulmonary structures, including the respiratory bronchioles.

The sympathetic and parasympathetic divisions of the autonomic nervous system innervate the respiratory system. Parasympathetic innervation causes airway constriction and an increase in respiratory secretions. Sympathetic innervation causes bronchial dilation and a decrease in respiratory tract secretions. There is no voluntary motor innervation of the lung, nor are there pain fibers. Pain fibers are found only in the pleura.

The lungs are encased in a thin, transparent, double-layered serous membrane called the pleura. A thin film of serous fluid separates the outer parietal and inner visceral pleural layers, allowing the two layers to glide over each other and yet hold together, allowing no separation between the lungs and the chest wall. The pleural cavity is a potential space in which serous fluid or inflammatory exudate can accumulate.
Basic Properties of Gases

The air we breathe is made up of a mixture of gases, mainly nitrogen and oxygen. These gases exert a combined pressure called the atmospheric or barometric pressure. The pressure at sea level, which is defined as 1 atmosphere, is 760 millimeters of mercury (mm Hg, or torr) or 14.7 pounds per square inch (PSI). When measuring respiratory pressures, atmospheric pressure is assigned a value of zero. A respiratory pressure of +15 mm Hg means that the pressure is 15 mm Hg above atmospheric pressure, and a respiratory pressure of −15 mm Hg is 15 mm Hg less than atmospheric pressure. Respiratory pressures often are expressed in centimeters of water (cm H2O) because of the small pressures involved (1 mm Hg = 1.35 cm H2O pressure).

The pressure exerted by a single gas in a mixture is called the partial pressure. The capital letter “P” followed by the chemical symbol of the gas (PO2) is used to denote its partial pressure. The law of partial pressures states that the total pressure of a mixture of gases, as in the atmosphere, is equal to the sum of the partial pressures of the different gases in the mixture. If the concentration of oxygen at 760 mm Hg (1 atmosphere) is 20%, its partial pressure is 152 mm Hg (760 × 0.20).

Air moves between the atmosphere and the lungs because of a pressure difference. According to the laws of physics, the pressure of a gas varies inversely with the volume of its container, provided the temperature remains constant. If equal amounts of a gas were placed in two different-sized containers, the pressure of the gas in the smaller container would be greater than the pressure in the larger container. The movement of gases is always from the container with the greater pressure to the one with the lesser pressure. The chest cavity can be viewed as a volume container. During inspiration, the size of the chest cavity increases and air moves into the lungs; during expiration, air moves out of the lungs as the size of the chest cavity decreases.

Ventilation and the Mechanics of Breathing

Ventilation is concerned with the movement of gases into and out of the lungs. There is nothing complicated about ventilation. It is a mechanical event that obeys the laws of physics as they relate to the behavior of gases. It relies on a system of open airways and the respiratory pressures created as the movements of the respiratory muscles change the size of the chest cage. The degree to which the lungs inflate and deflate depends on the respiratory pressures inflating the lung, compliance of the lungs, and airway resistance.

Respiratory Pressures

The pressure inside the airways and alveoli of the lungs is called the intrapulmonary pressure or alveolar pressure. The gases in this area of the lungs are in communication with atmospheric pressure (Fig. 35.11). When the glottis is open and air is not moving into or out of the lungs, as occurs just before inspiration or expiration, the intrapulmonary pressure is zero or equal to atmospheric pressure.

The pressure in the pleural cavity is called the intrapleural pressure. The intrapleural pressure of a normal inflated lung is always negative in relation to alveolar pressure, approximately −4 mm Hg between breaths when the glottis is open and the alveolar spaces are open to the atmosphere. The lungs and the chest wall have elastic properties, each pulling in the opposite direction. If removed from the chest, the lungs would contract to a smaller size, and the chest wall, if freed from the lungs, would expand. The opposing forces of the chest wall and lungs create a pull against the visceral and parietal layers of the pleura, causing the pressure in the pleural cavity to become negative. During inspiration, the elastic recoil of the lungs increases, causing intrapleural pressure to become more negative than during expiration. Without the negative
intrathoracic pressure holding the lungs against the chest wall, their elastic recoil properties would cause them to collapse. Although intrapleural pressure is negative in relation to alveolar pressure, it may become positive in relation to atmospheric pressure (e.g., during forced expiration and coughing). The transpulmonary (trans = “across”) pressure is the difference between the alveolar and intrapleural pressures and is used in determining pulmonary compliance.

The intrathoracic pressure is the pressure in the thoracic cavity. It is equal to the intrapleural pressure and is the pressure to which the lungs, heart, and great vessels are exposed. Forced expiration against a closed glottis, such as occurs during defecation and the Valsalva maneuver, produces marked increases in intrathoracic pressure and impedes venous return to the right atrium.

**Chest Cage and Respiratory Muscles**
The lungs and major airways share the chest cavity with the heart, great vessels, and esophagus. The chest cavity is a closed compartment bounded on the top by the neck muscles and at the bottom by the diaphragm. The outer walls of the chest cavity are formed by 12 pairs of ribs, the sternum, the thoracic vertebrae, and the intercostal muscles that lie between the ribs. Mechanically, the act of breathing depends on the fact that the chest cavity is a closed compartment whose only opening to the external atmosphere is through the trachea.

Ventilation consists of inspiration and expiration. During inspiration, the size of the chest cavity increases, the intrathoracic pressure becomes more negative, and air is drawn into the lungs. Expiration occurs as the elastic components of the chest wall and lung structures that were stretched during inspiration recoil, causing the size of the chest cavity to decrease and the pressure in the chest cavity to increase.

The diaphragm is the principal muscle of inspiration. When the diaphragm contracts, the abdominal contents are forced downward and the chest expands from top to bottom (Fig. 35.12). During normal levels of inspiration, the diaphragm moves approximately 1 cm, but this can be increased to 10 cm on forced inspiration. The diaphragm is innervated by the phrenic nerve roots, which arise from the cervical level of the spinal cord, mainly from C4 but also from C3 and C5. People who sustain spinal cord injury above C3 lose the function of the diaphragm and require mechanical ventilation. Paralysis of one side of the diaphragm causes the chest to move up on that side rather than down during inspiration because of the negative pressure in the chest. This is called paradoxical movement.

The external intercostal muscles, which also aid in inspiration, connect to the adjacent ribs and slope downward and forward (Fig. 35.13). When they contract, they raise the ribs and rotate them slightly so that the sternum is pushed forward. This enlarges the chest from side to side and from front to back. The intercostal muscles receive their innervation from nerves that exit the central nervous system at the thoracic level of the spinal cord. Paralysis of these muscles usually does not have a serious effect on respiration because of the effectiveness of the diaphragm.

The accessory muscles of inspiration include the scalene muscles and the sternocleidomastoid muscles. The scalene muscles elevate the first two ribs, and the sternocleidomastoid
molecules raise the sternum to increase the size of the chest cavity. These muscles contribute little to quiet breathing but contract vigorously during exercise. For the accessory muscles to assist in ventilation, they must be stabilized in some way. For example, people with bronchial asthma often brace their arms against a firm object during an attack as a means of stabilizing their shoulders so that the attached accessory muscles can exert their full effect on ventilation. The head commonly is bent backward so that the scalene and sternocleidomastoid muscles can elevate the ribs more effectively.

Expiration is largely passive. It occurs as the elastic components of the chest wall and lung structures that were stretched during inspiration recoil, causing air to leave the lungs as the intrathoracic pressure increases. When needed, the abdominal and the internal intercostal muscles can be used to increase expiratory effort (see Fig. 35.13B). The increase in intra-abdominal pressure that accompanies the forceful contraction of the abdominal muscles pushes the diaphragm upward and results in an increase in intra-thoracic pressure. The internal intercostal muscles move inward, which pulls the chest downward, increasing expiratory effort.

**Lung Compliance**

Lung compliance refers to the ease with which the lungs can be inflated. Compliance can be appreciated by comparing the ease of blowing up a noncompliant new balloon that is stiff and resistant with a compliant one that has been previously blown up and is easy to inflate. Specifically, lung compliance (C) describes the change in lung volume (ΔV) that can be accomplished with a given change in respiratory pressure (ΔP); thus, \( C = \frac{\Delta V}{\Delta P} \). It takes more pressure to move the same amount of air into a noncompliant lung than it does into a compliant one.

Lung compliance is determined by the elastin and collagen fibers of the lung, its water content, and surface tension. It also depends on the compliance of the thoracic or chest cage. It is diminished by conditions that reduce the natural elasticity of the lung, block the bronchi or smaller airways, increase the surface tension in the alveoli, or impair the flexibility of the thoracic cage.

**Elastin and Collagen Fibers.** Lung tissue is made up of elastin and collagen fibers. The elastin fibers are easily stretched and increase the ease of lung inflation, whereas the collagen fibers resist stretching and make lung inflation more difficult. In lung diseases such as interstitial lung disease and pulmonary fibrosis, the lungs become stiff and noncompliant as the elastin fibers are replaced with scar tissue. Pulmonary congestion and edema produce a reversible decrease in pulmonary compliance.

Elastic recoil describes the ability of the elastic components of the lung to recoil to their original position after having been stretched. Overstretching lung tissues, as occurs with emphysema, causes the elastic components of the lung to lose their recoil, making the lung easier to inflate but more difficult to deflate because of its inability to recoil.

**Surface Tension.** An important factor in lung compliance is the surface tension or attraction forces of the surface molecules in the alveoli. The alveoli are lined with a thin film of liquid, and it is at the interface between this liquid film and the alveolar air that surface tension develops. This is because the forces that hold the water molecules of the liquid film together are stronger than those that hold the air molecules in the alveoli together. In the alveoli, excess surface tension causes water molecules in the liquid film to contract, making lung inflation difficult.

The units of surface tension are those of force per unit length. The relationship between the pressure within a sphere such as an alveolus and the tension in the wall can be described using the law of Laplace (pressure = 2 × surface tension/radius). If the surface tension were equal throughout the lungs, the alveoli with the smallest radii would have the greatest pressure, and this would cause them to empty into the larger alveoli (Fig. 35.14A). The reason this does not occur is because of surface tension–lowering molecules, called surfactant, that line the inner surface of the alveoli.

Pulmonary surfactant is a complex mixture of phospholipids, neutral lipids, and proteins that is synthesized in the type II alveolar cells. Substances that are termed surfactants consist of two parts with opposing properties that are irreversibly bound to each other. One part is polar and seeks aqueous interfaces.

![Diagram of lung compliance](image-url)
fluid or hydrophilic (water-attracting) surfaces; the other is nonpolar and seeks oil, air, or hydrophobic (water-repelling) surfaces (see Fig. 35.14B). Pulmonary surfactant forms a monolayer, with its hydrophilic surface binding to liquid film on the surface of the alveoli and its hydrophobic surface facing outward toward the gases in the alveolar air. It is this monolayer that interrupts the surface tension that develops at the air–liquid interface in the alveoli.

Pulmonary surfactant, particularly SP-B, exerts several important effects on lung inflation. It lowers the surface tension and it increases lung compliance and ease of lung inflation. Without surfactant, lung inflation would be extremely difficult. In addition, it helps to keep the alveoli dry and prevent pulmonary edema. This is because water is pulled out of the pulmonary capillaries into the alveoli when increased surface tension causes the alveoli to contract. Surfactant also provides for stability and more even inflation of the alveoli. Alveoli, except those at the pleural surface, are surrounded by other alveoli. Thus, the tendency of one alveolus to collapse is opposed by the traction exerted by the surrounding alveolus. The surfactant molecules are also more densely packed in small alveoli than in large alveoli (see Fig. 35.14C). In postoperative and bedridden people, shallow and quiet breathing often impairs the spreading of surfactant. Encouraging these people to cough and deep breathe enhances the spreading of surfactant. This allows for a more even distribution of ventilation and prevention of atelectasis.

The type II alveolar cells that produce surfactant do not begin to mature until the 26th to 27th week of gestation; consequently, many premature infants have difficulty producing sufficient amounts of surfactant. This can lead to alveolar collapse and severe respiratory distress. This condition, called infant respiratory distress syndrome, is the single most common cause of respiratory disease in premature infants. Surfactant dysfunction also is possible in the adult. This usually occurs as the result of severe injury or infection and can contribute to the development of a condition called acute respiratory distress syndrome.

**Airway Airflow**

The volume of air that moves into and out of the air exchange portion of the lungs is directly related to the pressure difference between the lungs and the atmosphere. It is inversely related to the resistance that the air encounters as it moves through the airways. Depending on the velocity and pattern of flow, airflow can be laminar or turbulent.

**Laminar or streamlined airflow** occurs at low flow rates in which the air stream is parallel to the sides of the airway. With laminar flow, the air at the periphery must overcome the resistance to flow, and as a result, the air in the center of the airway moves faster. **Turbulent airflow** is disorganized flow in which the molecules of the gas move laterally, collide with one another, and change their velocities. Whether turbulence develops depends on the radius of the airways, the interaction of the gas molecules, and the velocity of airflow. It is most likely to occur when the radius of the airways is large and the velocity of flow is high. Turbulent flow occurs regularly in
the trachea. Turbulence of airflow accounts for the respiratory sounds that are heard during chest auscultation (i.e., listening to chest sounds using a stethoscope). In the bronchial tree with its many branches laminar airflow probably occurs only in the very small airways where the velocity of flow is low.

**Airway Resistance.** Airway resistance is the ratio of the pressure driving inspiration or expiration to airflow. The French physician Jean Léonard Marie Poiseuille first described the pressure–flow characteristics of laminar flow in a straight circular tube, a correlation that has become known as the **Poiseuille law.** According to the Poiseuille law, the resistance to flow is inversely related to the fourth power of the radius \( R = 1/r^4 \). If the radius is reduced by one half, the resistance increases 16-fold \( 2 \times 2 \times 2 \times 2 = 16 \).

Airway resistance differs in large (e.g., trachea and bronchi), medium-sized (e.g., segmental), and small (e.g., bronchioles) airways. Therefore, the total airway resistance is equal to the sum of the resistances in these three types of airways. The site of most of the resistance along the bronchial tree is the medium size bronchi, with the smallest airways contributing very little to the total airway resistance. This is because most of these airways are arranged in parallel and their resistances are added as reciprocals \( i.e., \text{total combined resistance} = 1/R + 1/R, \text{etc.} \). Although the resistance of each individual bronchiole may be relatively high, their great number results in a large total cross-sectional area, causing their total resistance to be low. Many airway diseases, such as emphysema and chronic bronchitis, begin in the small airways. Early detection of these diseases is often difficult because a considerable amount of damage must be present before the usual measurements of airway resistance can be detected.

Airway resistance is greatly affected by lung volumes. Resistance is less during inspiration than expiration. This is because elastic fibers connect the outside of the airways to the surrounding lung tissues. As a result, these airways are pulled open as the lungs expand during inspiration, and they become narrower as the lungs deflate during expiration (Fig. 35.15). This is one of the reasons why people with conditions that increase airway resistance, such as asthma (reactive airway), usually have less difficulty breathing during inspiration than during expiration.

Airway resistance is also affected by the bronchial smooth muscle tone that controls airway diameter. The smooth muscles in the airway, from the trachea down to the terminal bronchioles, are under autonomic nervous system control. Stimulation of the parasympathetic nervous system causes bronchial constriction as well as increased mucus secretion. Sympathetic stimulation has the opposite effect.

**Airway Compression During Forced Expiration.** Airway resistance does not change much during normal quiet breathing. However, it is significantly increased during forced expiration, such as in vigorous exercise. Airflow through the collapsible airways in the lungs depends on the distending airway (intrapulmonary) pressures that hold the airways open and the external (intrapleural or intrathoracic) pressures that surround and compress the airways. The difference between these two pressures (intrathoracic pressure minus airway pressure) is called the **transpulmonary pressure.** For airflow to occur, the distending pressure inside the airways must be greater than the compressing pressure outside the airways.

During forced expiration, the transpulmonary pressure is decreased because of a disproportionate increase in the intrathoracic pressure compared with airway pressure. The resistance that air encounters as it moves out of the lungs causes a further drop in airway pressure. If this drop in airway pressure is sufficiently great, the surrounding intrathoracic pressure will compress the collapsible airways (i.e., those that lack cartilaginous support), causing airflow to be interrupted and air to be trapped in the terminal airways (Fig. 35.16).

This type of airway compression usually is seen only during forced expiration in people with normal respiratory function. However, it may occur during normal breathing in people with lung diseases. For example, in conditions that increase airway resistance, such as emphysema, the pressure drop along the smaller airways is magnified, and an increase in intra-airway pressure is needed to maintain airway patency. Measures such as pursed-lip breathing increase airway pressure and improve expiratory flow rates in people with chronic obstructive pulmonary disease (COPD). This is also the basis for using positive end-expiratory pressure in people who are...
being mechanically ventilated. Infants who are having trouble breathing often grunt to increase their expiratory airway pressures and keep their airways open.

**Lung Volumes**

Lung volumes, or the amount of air exchanged during ventilation, can be subdivided into three components: (1) the tidal volume, (2) the inspiratory reserve volume, and (3) the expiratory reserve volume (Fig. 35.17). The **tidal volume** \((V_T)\) is the volume of air inspired (or exhaled) with each breath. It varies with age, gender, body position, and metabolic activity. It usually is about 500 mL in the average-sized adult and about 3 to 5 mL/kg in children. The maximum amount of air that can be inspired in excess of the normal \(V_T\) is called the **inspiratory reserve volume** \((IRV)\), and the maximum amount that can be exhaled in excess of the normal \(V_T\) is the **expiratory reserve volume** \((ERV)\). Approximately 1200 mL of air always remains in the lungs after forced expiration; this air is the **residual volume** \((RV)\). The RV increases with age because there is more trapping of air in the lungs at the end of expiration. These volumes can be measured using an instrument called a **spirometer**.

Lung capacities include two or more lung volumes. The **vital capacity** equals the IRV plus the \(V_T\) plus the ERV. This is the amount of air that can be exhaled from the point of maximal inspiration. The **inspiratory capacity** equals the \(V_T\) plus the IRV. It is the amount of air a person can breathe in beginning at the normal expiratory level and distending the lungs to the maximal amount. The **functional residual capacity** is the sum of the RV and ERV. It is the volume of air that remains in the lungs at the end of normal expiration. The **total lung capacity** is the sum of all the volumes in the lungs. The RV cannot be measured with the spirometer because this air cannot be expressed from the lungs. It is measured by indirect methods.

**FIGURE 35.17** • Tracings of respiratory volumes (left) and lung capacities (right) as they would appear if made using a spirometer. The tidal volume (yellow) represents the amount of air inhaled and exhaled during normal breathing; the inspiratory reserve volume (pink), the maximal amount of air in excess of the tidal volume that can be forcefully inhaled; the maximal expiratory reserve (blue), the maximal amount of air that can be exhaled in excess of the tidal volume; and the residual volume (green), the air that continues to remain in the lung after maximal expiratory effort. The inspiratory capacity represents the sum of the inspiratory reserve volume and the tidal volume; the functional residual capacity, the sum of the maximal expiratory reserve and residual volumes; and the total lung capacity, the sum of all the volumes.
such as the helium dilution method, nitrogen washout method, or body plethysmography.\textsuperscript{5} Lung volumes and capacities are summarized in Table 35.1.

### Pulmonary Function Studies

The previously described lung volumes and capacities are anatomic or static measures determined by lung volumes and measured without relation to time. The spirometer also is used to measure dynamic lung function (\textit{i.e.}, ventilation with respect to time). These tests often are used in assessing pulmonary function. Pulmonary function measures include maximum voluntary ventilation, forced vital capacity, forced expiratory volumes and flow rates, and forced inspiratory flow rates (Table 35.2). Pulmonary function is measured for various clinical purposes, including diagnosis of respiratory disease, preoperative surgical and anesthetic risk evaluation, and symptom and disability evaluation for legal or insurance purposes. The tests also are used for evaluating dyspnea, cough, wheezing, and abnormal radiologic or laboratory findings.

*By convention, all the lung volumes and rates of flow are expressed in terms of body temperature and pressure and saturated with water vapor (BTPS), which allows for a comparison of the pulmonary function data from laboratories with different ambient temperatures and altitudes.
The maximum voluntary ventilation measures the volume of air that a person can move into and out of the lungs during maximum effort lasting for 12 to 15 seconds. This measurement usually is converted to liters per minute. The forced vital capacity (FVC) involves full inspiration to total lung capacity followed by forceful maximal expiration. Obstruction of airways produces a FVC that is lower than that observed with more slowly performed vital capacity measurements. The forced expiratory volume (FEV) is the expiratory volume achieved in a given time period. The FEV, is the FEV that can be exhaled in 1 second. The FEV frequently is expressed as a percentage of the FVC. The FEV and FVC are used in the diagnosis of obstructive lung disorders.

The forced inspiratory vital flow (FIF) measures the respiratory response during rapid maximal inspiration. Calculation of airflow during the middle half of inspiration (FIF) relative to the forced midexpiratory flow rate (FEF) is used as a measure of respiratory muscle dysfunction because inspiratory flow depends more on effort than does expiration.

### Efficiency and the Work of Breathing

The minute volume, or total ventilation, is the amount of air that is exchanged in 1 minute. It is determined by the metabolic needs of the body. The minute volume is equal to the VT multiplied by the respiratory rate, which is normally about 6000 mL (500 mL VT × respiratory rate of 12 breaths/minute) in the average-sized adult during normal activity. The efficiency of breathing is determined by matching the VT and respiratory rate in a manner that provides an optimal minute volume while minimizing the work of breathing.

The work of breathing is determined by the amount of effort required to move air through the conducting airways and by the ease of lung expansion, or compliance. Expansion of the lungs is difficult for people with stiff and noncompliant lungs. They usually find it easier to breathe if they keep their VT low and breathe at a more rapid rate (e.g., 300 × 20 = 6000 mL) to achieve their minute volume and meet their oxygen needs. In contrast, people with obstructive airway disease usually find it less difficult to inflate their lungs but expend more energy in moving air through the airways. As a result, these people take deeper breaths and breathe at a slower rate (e.g., 600 × 10 = 6000 mL) to achieve their oxygen needs.

### IN SUMMARY

The movement of air between the atmosphere and the lungs follows the laws of physics as they relate to gases. The air in the alveoli contains a mixture of gases, including nitrogen, oxygen, carbon dioxide, and water vapor. With the exception of water vapor, each gas exerts a pressure that is determined by the atmospheric pressure and the concentration of the gas in the mixture. Water vapor pressure is affected by temperature but not atmospheric pressure. Air moves into the lungs along a pressure gradient. The pressure inside the airways and alveoli of the lungs is called intrapulmonary (or alveolar) pressure; the pressure in the pleural cavity is called pleural pressure; and the pressure in the thoracic cavity is called intrathoracic pressure.

Breathing is the movement of gases between the atmosphere and the lungs. It requires a system of open airways and pressure changes resulting from the action of the respiratory muscles in changing the volume of the chest cage. The diaphragm is the principal muscle of inspiration, assisted by the external intercostal muscles. The scalene and sternocleidomastoid muscles elevate the ribs and act as accessory muscles for inspiration. Expiration is largely passive, aided by the elastic recoil of the respiratory muscles that were stretched during inspiration. When needed, the abdominal and internal intercostal muscles can be used to increase expiratory effort.

Lung compliance describes the ease with which the lungs can be inflated. The elastic and collagen fibers of the lung, the water content, the surface tension of the alveoli, and the compliance of the chest wall determine lung compliance. It also reflects the surface tension at the air–epithelium interface of the alveoli. Surfactant molecules, produced by type II alveolar cells, reduce the surface tension in the lungs and thereby increase lung compliance.

The volume of air that moves into and out of the air exchange portion of the lungs is directly related to the pressure difference between the lungs and the atmosphere and inversely related to the resistance that the air encounters as it moves through the airways. Depending on the velocity and pattern of flow, airflow can be laminar or turbulent. Airway resistance refers to the impedance to flow that the air encounters as it moves through the airways. It differs with airway size, being greatest in the medium-sized bronchi and lowest in the smaller bronchioles.

Lung volumes and lung capacities reflect the amount of air that is exchanged during normal and forced breathing. The tidal volume (VT) is the amount of air that moves into and out of the lungs during normal breathing. The inspiratory reserve volume (IRV) is the maximum amount of air that can be inspired in excess of the normal VT. The expiratory reserve volume (ERV) is the maximum amount that can be exhaled in excess of the normal VT. The residual volume (RV) is the amount of air that remains in the lungs after forced expiration. Lung capacities include two or more lung volumes. The vital capacity equals the IRV plus the VT plus the ERV and is the amount of air that can be exhaled from the point of maximal inspiration. The minute volume, which is determined by the metabolic needs of the body, is the amount of air that is exchanged in 1 minute (i.e., respiratory rate and VT).
The primary functions of the lungs are oxygenation of the blood and removal of carbon dioxide. Pulmonary gas exchange is conventionally divided into three processes:

- Ventilation—the flow of gases into and out of the alveoli of the lungs
- Perfusion—the flow of blood in the adjacent pulmonary capillaries
- Diffusion—the transfer of gases between the alveoli and the pulmonary capillaries

The efficiency of gas exchange requires that alveolar ventilation occur adjacent to perfused pulmonary capillaries.

### Ventilation

Ventilation refers to the exchange of gases in the respiratory system. There are two types of ventilation: pulmonary and alveolar. *Pulmonary ventilation* refers to the total exchange of gases between the atmosphere and the lungs. *Alveolar ventilation* is the exchange of gases within the gas exchange portion of the lungs. Ventilation requires a system of open airways and a pressure difference that moves air into and out of the lungs. It is affected by body position and lung volume as well as by disease conditions that affect the heart and respiratory system.

#### Distribution of Ventilation

The distribution of ventilation between the apex and base of the lung varies with body position and the effects of gravity on intrapleural pressure (Fig. 35.18). In the seated or standing position, gravity exerts a downward pull on the lung, causing intrapleural pressure at the apex of the lung to become more negative than that at the base of the lung. As a result, the alveoli at the apex of the lung are more fully expanded than those at the base of the lung. The same holds true for dependent portions of the lung in the supine or lateral position. In the supine position, ventilation in the lowermost (posterior) parts of the lung exceeds that in the uppermost (anterior) parts. In the lateral position (i.e., lying on the side), the dependent lung is better ventilated.

### Dead Air Space

Dead space refers to the air that must be moved with each breath but does not participate in gas exchange. The movement...
of air through dead space contributes to the work of breathing but not to gas exchange. There are two types of dead space:

- Anatomic dead space: that contained in the conducting airways
- Alveolar dead space: that contained in the respiratory portion of the lung

The volume of anatomic airway dead space is fixed at approximately 150 to 200 mL, depending on body size. It constitutes air contained in the nose, pharynx, trachea, and bronchi. The creation of a tracheostomy (surgical opening in the trachea) decreases anatomic dead space ventilation because air does not have to move through the nasal and oral airways. Alveolar dead space, normally about 5 to 10 mL, constitutes alveolar air that does not participate in gas exchange. When alveoli are ventilated but deprived of blood flow, they do not contribute to gas exchange and thereby constitute alveolar dead space.

The physiologic dead space includes the anatomic dead space plus alveolar dead space. In people with normal respiratory function, physiologic dead space is about the same as anatomic dead space. Only in lung disease does physiologic dead space increase. Alveolar ventilation is equal to the minute ventilation minus the physiologic dead space ventilation.

**KEY POINTS**

**MATCHING OF VENTILATION AND PERFUSION**

- Exchange of gases between the air in the alveoli and the blood in pulmonary capillaries requires a matching of ventilation and perfusion.
- Dead air space refers to the volume of air that is moved with each breath but does not participate in gas exchange. Anatomic dead space is that contained in the conducting airways that normally do not participate in gas exchange. Alveolar dead space results from alveoli that are ventilated but not perfused.
- Shunt refers to blood that moves from the right to the left side of the circulation without being oxygenated. With an anatomic shunt, blood moves from the venous to the arterial side of the circulation without going through the lungs. Physiologic shunting results from blood moving through unventilated parts of the lung.

**Perfusion**

The primary functions of the pulmonary circulation are to perfuse or provide blood flow to the gas exchange portion of the lung and to facilitate gas exchange. The pulmonary circulation serves several important functions in addition to gas exchange. It filters all the blood that moves from the right to the left side of the circulation; it removes most of the thromboemboli that might form; and it serves as a reservoir of blood for the left side of the heart.

The gas exchange function of the lungs requires a continuous flow of blood through the respiratory portion of the lungs. Deoxygenated blood enters the lung through the pulmonary artery, which has its origin in the right side of the heart and enters the lung at the hilus, along with the primary bronchus. The pulmonary arteries branch in a manner similar to that of the airways. The small pulmonary arteries accompany the bronchi as they move down the lobules and branch to supply the capillary network that surrounds the alveoli (see Fig. 35.8). The oxygenated capillary blood is collected in the small pulmonary veins of the lobules. It then moves to the larger veins to be collected in the four large pulmonary veins that empty into the left atrium.

The pulmonary blood vessels are thinner, more compliant, and offer less resistance to flow than those in the systemic circulation. In addition, the pressures in the pulmonary system are much lower (e.g., 22/8 mm Hg versus 120/70 mm Hg pressure in systemic circulation). The low pressure and low resistance of the pulmonary circulation accommodate the delivery of varying amounts of blood from the systemic circulation without producing signs and symptoms of congestion. The volume in the pulmonary circulation is approximately 500 mL, with approximately 100 mL of this volume located in the pulmonary capillary bed. When the input of blood from the right heart and output of blood to the left heart are equal, pulmonary blood flow remains constant. Small differences between input and output can result in large changes in pulmonary volume if the differences continue for many heartbeats. The movement of blood through the pulmonary capillary bed requires that the mean pulmonary arterial pressure be greater than the mean pulmonary venous pressure. Pulmonary venous pressure increases in left-sided heart failure, allowing blood to accumulate in the pulmonary capillary bed and cause pulmonary edema.

**Distribution of Blood Flow**

As with ventilation, the distribution of pulmonary blood flow is affected by body position and gravity. In the upright position, the distance of the upper apices of the lung above the level of the heart may exceed the perfusion capabilities of the mean pulmonary arterial pressure (approximately 12 mm Hg). Therefore, blood flow in the upper part of the lungs is less than that in the base or bottom part of the lungs (Fig. 35.19). In the supine position, the lungs and the heart are at the same level, and blood flow to the apices and base of the lungs becomes more uniform. In this position, blood flow to the posterior or dependent portions (e.g., bottom of the lung when lying on the side) exceeds flow in the anterior or nondependent portions of the lungs.

**Hypoxia-Induced Vasoconstriction**

The blood vessels in the pulmonary circulation are highly sensitive to alveolar oxygen levels and undergo marked vasoconstriction when exposed to hypoxia. The precise mechanism for this response is unclear. When alveolar oxygen levels drop below 60 mm Hg, marked vasoconstriction may occur.
At very low oxygen levels, the local flow may be almost abolished. In regional hypoxia, which occurs with atelectasis, vasoconstriction is localized to a specific region of the lung. In this case, vasoconstriction has the effect of directing blood flow away from the hypoxic regions of the lungs. When alveolar hypoxia no longer exists, blood flow is restored.

Generalized hypoxia, which occurs at high altitudes and in people with chronic hypoxia due to lung disease, causes vasoconstriction throughout the lung. Prolonged hypoxia can lead to pulmonary hypertension and increased workload on the right heart, causing cor pulmonale. A low blood pH produces a similar effect, particularly when alveolar hypoxia is present (e.g., during circulatory shock).

**Shunt**

Shunt refers to blood that moves from the right to the left side of the circulation without being oxygenated. As with dead air space, there are two types of shunts: physiologic and anatomic. In an anatomic shunt, blood moves from the venous to the arterial side of the circulation without moving through the lungs. Anatomic intracardiac shunting of blood occurs with congenital heart defects. In a physiologic shunt, there is mismatching of ventilation and perfusion within the lung. This results in insufficient ventilation to provide the oxygen needed to oxygenate the blood flowing through the alveolar capillaries. Physiologic shunting of blood usually results from destructive lung disease that impairs ventilation or from heart failure that interferes with movement of blood through sections of the lungs.

**Mismatching of Ventilation and Perfusion**

The gas exchange properties of the lung depend on matching ventilation and perfusion, ensuring that equal amounts of air and blood are entering the respiratory portion of the lungs. Both dead air space and shunt produce a mismatching of ventilation and perfusion, as depicted in Figure 35.20. With shunt (depicted on the left), there is perfusion without ventilation, resulting in a low ventilation–perfusion ratio. It occurs in conditions such as atelectasis in which there is airway obstruction. With dead air space (depicted on the right), there is ventilation without perfusion, resulting in a high ventilation–perfusion ratio. It occurs in conditions such as pulmonary embolism, which impairs blood flow to a part of the lung. The arterial blood leaving the pulmonary circulation reflects mixing of blood from normally ventilated and perfused areas of the lung as well as areas that are not ventilated (dead air space) or perfused (shunt). Many of the conditions that cause mismatching of ventilation and perfusion involve both dead air space and shunt. In chronic obstructive lung disease, for example, there may be impaired ventilation in one area of the lung and impaired perfusion in another area.
In a person with pulmonary embolism like Ms. French, ventilation/perfusion mismatch occurs because blood flow to part of the lung is impaired. Ms. French’s increased respiratory rate is a clinical manifestation of her impaired gas exchange from the ventilation/perfusion mismatch.

**Diffusion**

Diffusion occurs in the respiratory portions of the lung and refers to the movement of gases across the alveolar–capillary membrane. The *Fick law of diffusion* can describe gas diffusion in the lung. The Fick law states the volume of a gas ($V_{gas}$) diffusing across the membrane per unit time is directly proportional to the partial pressure difference of the gas ($P_1 - P_2$), the surface area (SA) of the membrane, and the diffusion coefficient (D) and is inversely proportional to the thickness (T) of the membrane (Fig. 35.21).1

Several factors influence the diffusion of gases in the lung. The administration of high concentrations of oxygen increases the difference in partial pressure between the two sides of the membrane and increases the diffusion of the gas. Diseases that destroy lung tissue (i.e., surface area for diffusion) or increase the thickness of the alveolar–capillary membrane adversely influence the diffusing capacity of the lungs.

The removal of one lung, for example, reduces the diffusing capacity by one half. The thickness of the alveolar–capillary membrane and the distance for diffusion are increased in people with pulmonary edema or pneumonia. The characteristics of the gas and its molecular weight and solubility constitute the diffusion coefficient and determine how rapidly a gas diffuses through the respiratory membranes. For example, carbon dioxide diffuses 20 times more rapidly than oxygen because of its greater solubility in the respiratory membranes.

The diffusing capacity provides a measure of the rate of gas transfer in the lungs per partial pressure gradient. Because the initial alveolar–capillary difference for oxygen cannot be measured, carbon monoxide (CO) is used to determine the diffusing capacity. Measuring CO has several advantages:

- Its uptake is not limited by diffusion or blood flow.
- There is essentially no CO in venous blood.
- Its affinity for hemoglobin is 210 times that of oxygen, ensuring that its partial pressure will remain essentially zero in the pulmonary capillary.

The most common technique for making this measurement is the *single-breath test*. This test involves the inhalation of a single breath of dilute CO, followed by a breath-hold of 10 seconds. The diffusing capacity can be calculated using the lung volume and the percentage of CO in the alveoli at the beginning and end of the 10-second breath-hold.

**Oxygen and Carbon Dioxide Transport**

Although the lungs are responsible for the exchange of gases with the external environment, it is the blood that transports these gases between the lungs and body tissues. The blood carries oxygen and carbon dioxide in the physically dissolved state and in combination with hemoglobin. Carbon dioxide also is converted to bicarbonate and transported in that form.

Dissolved oxygen and carbon dioxide exert a partial pressure that is designated in the same manner as the partial pressures in the gas state. In the clinical setting, blood gas measurements are used to determine the partial pressure of oxygen ($PO_2$) and carbon dioxide ($PCO_2$) in the blood. Arterial blood commonly is used for measuring blood gases. Venous blood is not used because venous levels of oxygen and carbon dioxide reflect the metabolic demands of the tissues rather than the gas exchange function of the lungs. The $PO_2$ of arterial blood normally is above 80 mm Hg, and the $PCO_2$ is in the range of 35 to 45 mm Hg (Table 35.3). Normally, the ABGs are the same or nearly the same as the partial pressure of the gases in the alveoli. The arterial $PO_2$ often is written $PaO_2$, and the alveolar $PO_2$ as $PAO_2$, with the same types of designations.

being used for PCO₂. This text uses PO₂ and PCO₂ to designate both arterial and alveolar levels of the gases.

**Oxygen Transport**

Oxygen is transported in two forms:

- In chemical combination with hemoglobin
- In the dissolved state

Hemoglobin carries about 98% to 99% of oxygen in the blood and is the main transporter of oxygen. The remaining 1% to 2% of the oxygen is carried in the dissolved state. Only the dissolved form of oxygen passes through the capillary wall, diffuses through the cell membrane, and makes itself available for use in cell metabolism. The oxygen content (measured in mL/100 mL) of the blood includes the oxygen carried by hemoglobin and in the dissolved state.

**Hemoglobin Transport.** Hemoglobin is a highly efficient carrier of oxygen. Hemoglobin with bound oxygen is called oxyhemoglobin. When oxygen is removed, it is called deoxygenated or reduced hemoglobin. Each gram of hemoglobin carries approximately 1.34 mL of oxygen when it is fully saturated. This means that a person with a hemoglobin level of 14 g/100 mL carries 18.8 mL of oxygen per 100 mL of blood.

In the lungs, oxygen moves across the alveolar–capillary membrane, through the plasma, and into the red blood cell, where it forms a loose and reversible bond with the hemoglobin molecule. In normal lungs, this process is rapid. Therefore, even with a fast heart rate the hemoglobin is almost completely saturated with oxygen during the short time it spends in the pulmonary capillaries. As the oxygen moves out of the capillaries in response to the needs of the tissues, the hemoglobin saturation drops. It is approximately 95% to 97% saturated as the blood leaves the left side of the heart. It then drops to approximately 75% saturation as the mixed venous blood returns to the right side of the heart.

**Dissolved Oxygen.** The partial pressure of oxygen represents the level of dissolved oxygen in plasma. The amount of dissolved oxygen depends on its partial pressure and its solubility in the plasma. In the normal lung at 760 mm Hg atmospheric pressure, the PO₂ of arterial blood is approximately 100 mm Hg. The solubility of oxygen in plasma is fixed and very small. For every 1 mm Hg of PO₂ present, 0.003 mL of oxygen becomes dissolved in 100 mL of plasma. This means that at a normal arterial PO₂ of 100 mm Hg, the blood carries only 0.3 mL of dissolved oxygen in each 100 mL of plasma. This amount (approximately 1%) is very small compared with the amount that can be carried in an equal amount of blood when oxygen is attached to hemoglobin.

However, this small amount can become a lifesaving mode of transport in cases of CO poisoning, when most of the hemoglobin sites are occupied by CO and are unavailable for transport of oxygen. The use of a hyperbaric chamber, in which 100% oxygen can be administered at high atmospheric pressures, increases the amount of oxygen that can be carried in the dissolved state and is used for people with severe burns, especially those impacting the respiratory system, and in people with multiple types of wounds such as the immunosuppressed or those with diabetes who have trouble healing.

**Binding Affinity of Hemoglobin for Oxygen.** The efficiency of the hemoglobin transport system depends on the ability of the hemoglobin molecule to bind oxygen in the lungs and release it as it is needed in the tissues. Oxygen that remains bound to hemoglobin cannot participate in tissue metabolism. The term affinity refers to hemoglobin’s ability to bind oxygen. Hemoglobin binds oxygen more readily when its affinity is increased and releases it more readily when its affinity is decreased.

The hemoglobin molecule is composed of four polypeptide chains with an iron-containing heme group. Because oxygen binds to the iron atom, each hemoglobin molecule can bind four molecules of oxygen when it is fully saturated. Oxygen binds cooperatively with the heme groups on the hemoglobin molecule. After the first molecule of oxygen binds to hemoglobin, the molecule undergoes a change in shape. As a result, the second and third molecules bind more readily, and binding of the fourth molecule is even easier. In a like manner, the unloading of the first molecule of oxygen enhances the unloading of the next molecule and so on. Thus, the affinity of hemoglobin for oxygen changes with hemoglobin saturation.

Hemoglobin’s affinity for oxygen is also influenced by pH, carbon dioxide concentration, and body temperature. It binds oxygen more readily under conditions of increased pH (alkalosis), decreased carbon dioxide concentration, and decreased body temperature, and it releases it more readily under conditions of decreased pH (acidosis), increased carbon dioxide concentration, and fever. For example, increased tissue metabolism generates carbon dioxide and metabolic acids and thereby decreases the affinity of hemoglobin for oxygen. Heat also is a by-product of tissue metabolism, explaining the effect of fever on oxygen binding. Red blood cells contain a metabolic intermediate called 2,3-diphosphoglycerate (2,3-DPG) that also affects the affinity of hemoglobin for oxygen. An increase in 2,3-DPG enhances unloading of oxygen from hemoglobin at the tissue level. Conditions that increase 2,3-DPG include exercise, hypoxia that occurs at high altitude, and chronic lung disease.

**The Oxygen Dissociation Curve.** The relation between the oxygen carried in combination with hemoglobin and the PO₂ of the blood is described by the oxygen–hemoglobin dissociation curve, which is shown in Figure 35.22. The x-axis of the graph depicts the PO₂ or dissolved oxygen. It reflects the partial pressure of the oxygen in the lungs (i.e., the PO₂ is approximately 100 mm Hg when room air is being breathed, but can rise to 200 mm Hg or higher when oxygen-enriched air is breathed). The left y-axis depicts hemoglobin saturation or the amount of oxygen that is carried by the hemoglobin. The right y-axis depicts oxygen content or total amount of the oxygen content being carried in the blood.

The S-shaped oxygen dissociation curve has a flat top portion representing binding of oxygen to hemoglobin in the lungs and a steep portion representing its release into the
Chapter 35  Structure and Function of the Respiratory System

Understanding Oxygen Transport

All body tissues rely on oxygen (O2) that is transported in the blood to meet their metabolic needs. Oxygen is carried in two forms: dissolved and bound to hemoglobin. About 98% of O2 is carried by hemoglobin, and the remaining 2% is carried in the dissolved state. Dissolved oxygen is the only form that diffuses across cell membranes and produces a partial pressure (PO2), which, in turn, drives diffusion. The transport of O2 involves (1) transfer from the alveoli to the pulmonary capillaries in the lung, (2) hemoglobin binding and transport, and (3) the dissociation from hemoglobin in the tissue capillaries.

Alveoli-to-Capillary Transfer

In the lung, O2 moves from the alveoli to the pulmonary capillaries as a dissolved gas. Its movement occurs along a concentration gradient. It moves from the alveoli, where the partial pressure of PO2 is about 100 mm Hg, to the venous end of the pulmonary capillaries with their lesser O2 concentration and lower PO2. The dissolved O2 moves rapidly between the alveoli and the pulmonary capillaries, such that the PO2 at the arterial end of the capillary is almost, if not exactly, the same as that in the alveoli.

Hemoglobin Binding and Transport

Oxygen, which is relatively insoluble in plasma, relies on hemoglobin for transport in the blood. Once oxygen has diffused into the pulmonary capillary, it moves rapidly into the red blood cells and reversibly binds to hemoglobin to form HbO2. The hemoglobin molecule contains four heme units, each capable of attaching an oxygen molecule. Hemoglobin is 100% saturated when all four units are occupied and is usually about 97% saturated in the systemic arterial blood. The capacity of the blood to carry O2 is dependent both on hemoglobin levels and the ability of the lungs to oxygenate the hemoglobin.

Continued
Oxygen Dissociation in the Tissues

The dissociation or release of O₂ from hemoglobin occurs in the tissue capillaries where the PO₂ is less than that of the arterial blood. As oxygen dissociates from hemoglobin, it dissolves in the plasma and then moves into the tissues where the PO₂ is less than that in the capillaries. The affinity of hemoglobin for O₂ is influenced by the carbon dioxide (PCO₂) content of the blood and its pH temperature and 2,3-diphosphoglycerate (2,3-DPG), a by-product of glycolysis in red blood cells. Under conditions of high metabolic demand, in which the PCO₂ is increased and the pH is decreased, the binding affinity of hemoglobin is decreased. During decreased metabolic demand, when the PCO₂ is decreased and the pH is increased, the affinity is increased.

The S shape of the curve reflects the effect that oxygen saturation has on the conformation of the hemoglobin molecule and its affinity for oxygen. At approximately 100 mm Hg PO₂, a plateau occurs. At this point the hemoglobin is approximately 98% saturated. Increasing the alveolar PO₂ above this level does not increase the hemoglobin saturation. Even at high altitudes, when the partial pressure of oxygen is considerably decreased, the hemoglobin remains relatively well saturated. At 60 mm Hg PO₂, for example, the hemoglobin is still approximately 89% saturated.

The steep portion of the dissociation curve—between 60 and 40 mm Hg—represents the removal of oxygen from the hemoglobin as it moves through the tissue capillaries. This portion of the curve reflects a considerable transfer of oxygen from hemoglobin to the tissues with only a small drop in PO₂. This ensures a gradient for oxygen to move into body cells. The tissues normally remove approximately 5 mL of oxygen per 100 mL of blood, and the hemoglobin of mixed venous blood is approximately 75% saturated as it returns to the right side of the heart. In this portion of the dissociation curve (saturation <75%), the rate at which oxygen is released from hemoglobin is determined largely by tissue uptake. During strenuous exercise, for example, the muscle cells may remove as much as 15 mL of oxygen per 100 mL of blood from hemoglobin.

Hemoglobin can be regarded as a buffer system that regulates the delivery of oxygen to the tissues. In order to function as a buffer system, the affinity of hemoglobin for oxygen must change with the metabolic needs of the tissues. This change is represented by a shift to the right or left in the dissociation curve (see Fig. 35.22B). A shift to the right indicates that the tissue PO₂ is greater for any given level of hemoglobin saturation and represents reduced affinity of the hemoglobin for oxygen at any given PO₂. It usually is caused by conditions that reflect increased tissue metabolism, such as fever or acidosis, or by an increase in PCO₂. High altitude and conditions such as pulmonary insufficiency, heart failure, and severe anemia also cause the oxygen dissociation curve to shift to the right. A shift to the left in the oxygen dissociation curve represents an increased affinity of hemoglobin for oxygen. It occurs in situations associated with a decrease in tissue metabolism, such as alkalosis, decreased body temperature, and decreased PCO₂ levels. The degree of shift can be determined by the P₅₀, or the partial pressure of oxygen that is needed to achieve a 50% saturation of hemoglobin. Returning to Figure 35.23B, the dissociation curve on the left has a P₅₀ of approximately 20 mm Hg; the normal curve, a P₅₀ of 26 mm Hg; and the curve on the right, a P₅₀ of 39 mm Hg.

The oxygen content (measured in mL/dL blood) represents the total amount of oxygen carried in the blood, including the dissolved oxygen and that carried by the hemoglobin (see Fig. 35.22C). The amount of hemoglobin-bound oxygen is determined by the concentration of hemoglobin (in g/dL), the oxygen-binding capacity of hemoglobin (1.34 mL O₂/g hemoglobin), and the percentage saturation of the hemoglobin. The dissolved oxygen content is the product of the oxygen solubility (0.0003 mL O₂/dL) times the PO₂. Thus, an anemic person may have a normal PO₂ and hemoglobin saturation level but decreased oxygen content because of the lower amount of hemoglobin for binding oxygen.
Carbon Dioxide Transport

Carbon dioxide is transported in the blood in three forms:

- As dissolved carbon dioxide (10%)
- Attached to hemoglobin (30%)
- As bicarbonate (60%)

Acid–base balance is influenced by the amount of dissolved carbon dioxide and the bicarbonate level in the blood.

As carbon dioxide is formed during the metabolic process, it diffuses out of cells into the tissue spaces and then into the capillaries. The partial pressure of the gas and its solubility coefficient (0.03 mL/100 mL/1 mm Hg PCO₂) determine the amount of dissolved carbon dioxide that can be carried in plasma. Carbon dioxide is 20 times more soluble in plasma than oxygen. Thus, the dissolved state plays a greater role in transport of carbon dioxide compared with oxygen.

Most of the carbon dioxide diffuses into the red blood cells, where it either forms carbonic acid or combines with hemoglobin. *Carbonic acid* (H₂CO₃) is formed when carbon dioxide combines with water (CO₂ + H₂O = H⁺ + HCO₃⁻). The process is catalyzed by an enzyme called *carbonic anhydrase*, which is present in large quantities in red blood cells. Carbonic anhydrase increases the rate of the reaction between carbon dioxide and water approximately 5000-fold. Carbonic acid readily ionizes to form bicarbonate (HCO₃⁻) and hydrogen (H⁺) ions. The hydrogen ion combines with the hemoglobin, which is a powerful acid–base buffer, and the bicarbonate ion diffuses into plasma in exchange for a chloride ion. This exchange is made possible by a special bicarbonate–chloride carrier protein in the red blood cell membrane. As a result of the bicarbonate–chloride shift, the chloride and water content of the red blood cell is greater in venous blood than in arterial blood.

In addition to the carbonic anhydrase–mediated reaction with water, carbon dioxide reacts directly with hemoglobin to form carbaminohemoglobin. The combination of carbon dioxide with hemoglobin is a reversible reaction that involves a loose bond. This allows transport of carbon dioxide from tissues to the lungs, where it is released into the alveoli for exchange with the external environment. The release of oxygen from hemoglobin in the tissues enhances the binding of carbon dioxide to hemoglobin. In the lungs, the combining of oxygen with hemoglobin displaces carbon dioxide. The binding of carbon dioxide to hemoglobin is determined by the acidic nature of hemoglobin. Binding with carbon dioxide causes the hemoglobin to become a stronger acid. In the lungs, the highly acidic hemoglobin has a lesser tendency to form carbaminohemoglobin, and carbon dioxide is released from hemoglobin into the alveoli. In the tissues, the release of oxygen from hemoglobin causes hemoglobin to become less acidic, thereby increasing its ability to combine with carbon dioxide and form carbaminohemoglobin.

**IN SUMMARY**

The primary functions of the lungs are oxygenation of the blood and removal of carbon dioxide. Pulmonary gas exchange is conventionally divided into three processes:
Ventilation, or the flow of gases into the alveoli of the lungs; perfusion, or movement of blood through the adjacent pulmonary capillaries; and diffusion, or transfer of gases between the alveoli and the pulmonary capillaries.

Ventilation is the movement of air between the atmosphere and the lungs and perfusion is the flow of blood into and out of the gas exchange portions of the lung. Pulmonary ventilation refers to the total exchange of gases between the atmosphere and the lungs, and alveolar ventilation to ventilation in the gas exchange portion of the lungs. The distribution of alveolar ventilation and pulmonary capillary blood flow varies with lung volume and body position. In the upright position and at high lung volumes, ventilation is greatest in the lower parts of the lungs. The upright position also produces a decrease in blood flow to the upper parts of the lung, resulting from the distance above the level of the heart and the low mean arterial pressure in the pulmonary circulation. The efficiency of gas exchange requires matching of ventilation and perfusion, so that equal amounts of air and blood enter the respiratory portion of the lungs. Two conditions interfere with matching of ventilation and perfusion: dead air space, in which areas of the lungs are ventilated but not perfused, and shunt, in which areas of the lungs are perfused but not ventilated.

The diffusion of gases in the lungs is influenced by four factors: the surface area available for diffusion; the thickness of the alveolar–capillary membrane, through which the gases diffuse; the differences in the partial pressure of the gas on either side of the membrane; and the diffusion characteristics of the gas.

The blood transports oxygen to the cells and returns carbon dioxide to the lungs. Oxygen is transported in two forms: in chemical combination with hemoglobin and physically dissolved in plasma (PO₂). Hemoglobin is an efficient carrier of oxygen. Approximately 98% to 99% of oxygen is transported in this manner. The relationship between the oxygen carried in combination with hemoglobin and the oxygen–hemoglobin dissociation curve describes the PO₂ of the blood. Carbon dioxide is carried in three forms: attached to hemoglobin (30%), dissolved carbon dioxide (10%), and bicarbonate (60%).

**CONTROL OF BREATHING**

After completing this section of the chapter, you should be able to meet the following objectives:

- Compare the neural control of the respiratory muscles, which control breathing, with that of cardiac muscle, which controls the pumping action of the heart.
- Trace the integration of the cough reflex from stimulus to explosive expulsion of air that constitutes the cough.
- Define dyspnea and list three types of conditions in which dyspnea occurs.

Unlike the heart, which has inherent rhythmic properties and can beat independently of the nervous system, the muscles that control respiration require continuous input from the nervous system. Movement of the diaphragm, intercostal muscles, sternocleidomastoid, and other accessory muscles that control ventilation is integrated by neurons located in the pons and medulla. These neurons are collectively referred to as the respiratory center (Fig. 35.23).

**Respiratory Center**

The respiratory center consists of two dense, bilateral aggregates of respiratory neurons. These neurons are involved in initiating inspiration and expiration and incorporating afferent impulses into motor responses of the respiratory muscles. The first, or dorsal, group of neurons in the respiratory center is concerned primarily with inspiration. These neurons control the activity of the phrenic nerves that innervate the diaphragm and drive the second, or ventral, group of respiratory neurons. They are thought to integrate sensory input from the lungs and airways into the ventilatory response. The second group of neurons, which contains inspiratory and expiratory neurons, controls the spinal motor neurons of the intercostal and abdominal muscles.

The pacemaker properties of the respiratory center result from the cycling of the two groups of respiratory neurons: the pneumotaxic center in the upper pons and the apneustic center in the lower pons (see Fig. 35.23). These two groups of neurons contribute to the function of the respiratory center in the medulla. The apneustic center has an excitatory effect on inspiration, tending to prolong inspiration. The pneumotaxic center switches inspiration off, assisting in the control of respiratory rate and inspiratory volume. Brain injuries that damage the connection between the pneumotaxic and apneustic centers result in an irregular breathing pattern that consists of prolonged inspiratory gasps interrupted by expiratory efforts.

Axons from the neurons in the respiratory center cross in the midline and descend in the ventrolateral columns of the spinal cord. The tracts that control inspiration and expiration are spatially separated in the cord, as are the tracts that transmit specialized reflexes (i.e., coughing and hiccupping) and voluntary control of ventilation. Only at the level of the spinal cord are the respiratory impulses integrated to produce a reflex response.

**Regulation of Breathing**

The control of breathing has automatic and voluntary components. The automatic regulation of ventilation is controlled by input from two types of sensors or receptors: chemoreceptors and lung receptors. Chemoreceptors monitor blood levels of oxygen, carbon dioxide, and pH and adjust ventilation to meet the changing metabolic needs of the body. Lung receptors monitor breathing patterns and lung function.

Voluntary regulation of ventilation integrates breathing with voluntary acts such as speaking, blowing, and singing. These acts, which are initiated by the motor and premotor cortex, cause a temporary suspension of automatic breathing. The automatic and voluntary components of respiration are
regulated by afferent impulses transmitted to the respiratory center from a number of sources. Afferent input from higher brain centers is evidenced by the fact that a person can consciously alter the depth and rate of respiration. Fever, pain, and emotion exert their influence through lower brain centers. Vagal afferents from sensory receptors in the lungs and airways are integrated in the dorsal area of the respiratory center.

Chemoreceptors

Tissue needs for oxygen and the removal of carbon dioxide are regulated by chemoreceptors that monitor blood levels of these gases. Input from these sensors is transmitted to the respiratory center, and ventilation is adjusted to maintain the ABGs within a normal range.

There are two types of chemoreceptors: central and peripheral. The most important chemoreceptors for sensing changes in the PCO₂ of the blood are the central chemoreceptors, which are located in chemosensitive regions near the respiratory center in the medulla. The central chemoreceptors are surrounded by brain extracellular fluid and respond to changes in its hydrogen ion (H⁺) concentration. The composition of the extracellular fluid surrounding the chemoreceptors is governed by the cerebral spinal fluid (CSF), local blood flow, and tissue metabolism. Of these, the CSF is apparently the most important. The CSF is separated from the blood by the blood–brain barrier, which permits free diffusion of carbon dioxide but not bicarbonate (HCO₃⁻) or H⁺. The carbon dioxide combines rapidly with water to form carbonic acid (H₂CO₃), which dissociates into H⁺ and HCO₃⁻. When the PCO₂ rises, carbon dioxide from the blood diffuses into the CSF, liberating H⁺, which then stimulates the chemoreceptors. The central chemoreceptors are extremely sensitive to short-term changes in PCO₂. An increase in PCO₂ levels produces an increase in ventilation that reaches its peak within a minute or so and then declines if the PCO₂ level remains elevated. Thus, people with chronically elevated levels of PCO₂ no longer have a response to this stimulus for increased ventilation but rely on the stimulus provided by a decrease in blood PO₂ levels. This occurs commonly with people who have COPD and is referred to as CO₂ narcosis.

The peripheral chemoreceptors are located in the carotid and aortic bodies, which are found at the bifurcation of the common carotid arteries and in the arch of the aorta, respectively (see Fig. 35.23). These chemoreceptors monitor arterial blood oxygen levels. Although the peripheral chemoreceptors also monitor carbon dioxide, they play a much more important role in monitoring oxygen levels. These receptors exert little control over ventilation until the PO₂ has dropped below 60 mm Hg. Thus, hypoxia is the main stimulus for ventilation in people with chronically elevated levels of carbon dioxide. If these people are given oxygen therapy at a level sufficient to increase the PO₂ above that needed to stimulate the peripheral chemoreceptors, their ventilation may be seriously depressed.

Lung Receptors

Lung and chest wall receptors monitor the status of breathing in terms of airway resistance and lung expansion. There are three types of lung receptors: stretch, irritant, and juxtacapillary receptors.
Stretch receptors are located in the smooth muscle layers of the conducting airways. They respond to changes in pressure in the walls of the airways. When the lungs are inflated, these receptors inhibit inspiration and promote expiration. They are important in establishing breathing patterns and minimizing the work of breathing by adjusting respiratory rate and VT to accommodate changes in lung compliance and airway resistance.

The irritant receptors are located between the airway epithelial cells. They are stimulated by noxious gases, cigarette smoke, inhaled dust, and cold air. Stimulation of the irritant receptors leads to airway constriction and a pattern of rapid, shallow breathing. This pattern of breathing probably protects respiratory tissues from the damaging effects of toxic inhalants. It also is thought that the mechanical stimulation of these receptors may ensure more uniform lung expansion by initiating periodic sighing and yawning. It is also possible that these receptors are involved in the bronchoconstriction response that occurs in some people with bronchial asthma.

The juxtacapillary or J receptors are located in the alveolar wall, close to the pulmonary capillaries. It is thought that these receptors sense lung congestion. These receptors may be responsible for the rapid, shallow breathing that occurs with pulmonary edema, pulmonary embolism, and pneumonia.

Cough Reflex

Coughing is a neurally mediated reflex that protects the lungs from accumulation of secretions and from entry of irritating and destructive substances. It is one of the primary defense mechanisms of the respiratory tract. The cough reflex is initiated by receptors located in the tracheobronchial wall. These receptors are extremely sensitive to irritating substances and to the presence of excess secretions. Afferent impulses from these receptors are transmitted through the vagus to the medullary center, which integrates the cough response.

Coughing itself requires the rapid inspiration of a large volume of air (usually about 2.5 L), followed by rapid closure of the glottis and forceful contraction of the abdominal and expiratory muscles. As these muscles contract, intrathoracic pressures are elevated to levels of 100 mm Hg or more. The rapid opening of the glottis at this point leads to an explosive expulsion of air.

Many conditions can interfere with the cough reflex and its protective function. The reflex is impaired in people whose abdominal or respiratory muscles are weak. This problem can be caused by disease conditions that lead to muscle weakness or paralysis, by prolonged inactivity, or as an outcome of surgery involving these muscles. Bed rest interferes with expansion of the chest and limits the amount of air that can be taken into the lungs in preparation for coughing, making the cough weak and ineffective. Disease conditions that prevent effective closure of the glottis and laryngeal muscles interfere with production of the marked increase in intrathoracic pressure that is needed for effective coughing. The presence of a nasogastric tube, for example, may prevent closure of the upper airway structures and may fatigue the receptors for the cough reflex that are located in the area. The cough reflex also is impaired when there is depressed function of the medullary centers in the brain that integrate the cough reflex. Interruption of the central integration aspect of the cough reflex can arise as the result of disease of this part of the brain or the action of drugs that depress the cough center.

Dyspnea

Dyspnea is a subjective sensation or a person’s perception of difficulty in breathing that includes the perception of labored breathing and the reaction to that sensation. The terms dyspnea, breathlessness, and shortness of breath (SOB) often are used interchangeably. Dyspnea is observed in at least three major cardiopulmonary disease states:

- Primary lung diseases, such as pneumonia, asthma, and emphysema
- Heart disease that is characterized by pulmonary congestion
- Neuromuscular disorders, such as myasthenia gravis and muscular dystrophy, that affect the respiratory muscles

Although dyspnea commonly is associated with respiratory disease, it also occurs for some people only during exercise and is referred to as exercise-induced reactive airway disorder or exercise-induced asthma.

The cause of dyspnea is unknown. Four types of mechanisms have been proposed to explain the sensation:

- Stimulation of lung receptors
- Increased sensitivity to changes in ventilation perceived through central nervous system mechanisms
- Reduced ventilatory capacity or breathing reserve
- Stimulation of neural receptors in the muscle fibers of the intercostals and diaphragm and of receptors in the skeletal joints

The first of the suggested mechanisms is stimulation of lung receptors. These receptors are stimulated by the contraction of bronchial smooth muscle, the stretch of the bronchial wall, pulmonary congestion, and conditions that decrease lung compliance. The second category of proposed mechanisms focuses on central nervous system mechanisms that transmit information to the cortex regarding respiratory muscle weakness or a discrepancy between the increased effort of breathing and inadequate respiratory muscle contraction. The third type of mechanism focuses on a reduction in ventilatory capacity or breathing reserve. A reduction in breathing reserve (i.e., maximum voluntary ventilation not being used during a given activity) to less than 65% to 75% usually correlates well with dyspnea. The fourth possible mechanism is stimulation of muscle and joint receptors in the respiratory musculature because of a discrepancy in the tension generated by these muscles and the VT that results. These receptors, once stimulated, transmit signals that bring about an awareness of the
breathing discrepancy. Like other subjective symptoms, such as fatigue and pain, dyspnea is difficult to quantify because it relies on a person’s perception of the problem.

The most common method for measuring dyspnea is a retrospective self-perceived determination of the level of daily activity at which a person experiences dyspnea. Several scales are available for this use. One of these uses four grades of dyspnea to evaluate disability. The visual analog scale may be used to assess breathing difficulty that occurs with a given activity, such as walking a certain distance. The visual analog scale consists of a continuum line (often 10 cm in length) with descriptors such as “easy to breathe” on one end and “very difficult to breathe” on the other. The person being assessed selects a point on the scale that describes his or her perceived dyspnea.

The treatment of dyspnea depends on the cause. For example, people with impaired respiratory function may require oxygen therapy, and those with pulmonary edema may require measures to improve heart function. Methods to decrease anxiety, breathing retraining, and energy conservation measures may be used to decrease the subjective sensation of dyspnea.

**IN SUMMARY**

The respiratory system requires continuous input from the nervous system. Movement of the diaphragm, intercostal muscles, and other respiratory muscles is controlled by neurons of the respiratory center located in the pons and medulla. The control of breathing has automatic and voluntary components. The automatic regulation of ventilation is controlled by two types of receptors: lung receptors, which protect respiratory structures, and chemoreceptors, which monitor the gas exchange function of the lungs by sensing changes in blood levels of carbon dioxide, oxygen, and pH. There are three types of lung receptors: stretch receptors, which monitor lung inflation; irritant receptors, which protect against the damaging effects of toxic inhalants; and J receptors, which are thought to sense lung congestion. There are two groups of chemoreceptors: central and peripheral. The central chemoreceptors are the most important in sensing changes in carbon dioxide levels, and the peripheral chemoreceptors function in sensing arterial blood oxygen levels.

Voluntary respiratory control is needed for integrating breathing and actions such as speaking, blowing, and singing. These acts, which are initiated by the motor and premotor cortex, cause temporary suspension of automatic breathing. The cough reflex protects the lungs from the accumulation of secretions and from the entry of irritating and destructive substances; it is one of the primary defense mechanisms of the respiratory tract. Dyspnea is a subjective sensation of difficulty in breathing that is seen in cardiac, pulmonary, and neuromuscular disorders that affect the respiratory muscles.

**REFERENCES**

Visit thePoint http://thePoint.lww.com for animations, journal articles, and more!
Respiratory illnesses represent one of the more common reasons for visits to the physician, admission to the hospital, and forced inactivity among all age groups. The common cold, although not usually serious, is a frequent cause of missed work and school days. Pneumonia is the sixth leading cause of death in the United States, particularly among the elderly and those with compromised immune function. In addition, it is the first cause of death among children in the world. Tuberculosis remains one of the deadliest diseases in the world and affects one third of the world population. A large number of people have multidrug-resistant TB, and many are immunocompromised. Immunocompromised people experience all types of bacterial, viral, and fungal infections. The most frequently seen fungal infections include histoplasmosis, coccidioidomycosis, and blastomycosis. Lung cancer remains the leading cause of cancer death worldwide. Children with upper and lower airway infections represent a large number of visits to primary care providers. Premature infants, especially those who experience respiratory distress syndrome (RDS), are at high risk for chronic respiratory infections and other complications such as bronchopulmonary dysplasia.
The respiratory tract is susceptible to infectious processes caused by multiple types of microorganisms. Infections can involve the upper respiratory tract (i.e., nose, oropharynx, and larynx), the lower respiratory tract (i.e., lower airways and lungs), or the upper and lower airways. For the most part, the signs and symptoms of respiratory tract infections depend on the function of the structure involved, the severity of the infectious process, and the person’s age and general health status. The discussion in this section of the chapter focuses on the common cold, rhinosinusitis, influenza, pneumonia, tuberculosis, and fungal infections of the lung. Acute respiratory infections in children are discussed in the last section of the chapter.

Viruses are the most frequent cause of respiratory tract infections. They can cause infections ranging from a self-limited cold to life-threatening pneumonia. Moreover, viral infections can damage bronchial epithelium, obstruct airways, and lead to secondary bacterial infections. Each viral species has its own pattern of respiratory tract involvement. For example, the rhinoviruses grow best at 33°C to 35°C and remain strictly confined to the upper respiratory tract. Viruses are able to move from the nasal cavity to the upper airways by binding to the intercellular adhesion molecule (ICAM-1). People with compromised immunological response are most susceptible to having a virus cause serious gas exchange or ventilation problems.

Other microorganisms, such as bacteria (e.g., pneumococci, staphylococci, mycobacteria, Mycobacterium tuberculosis), fungi (e.g., Histoplasma capsulatum [histoplasmosis], Coccioides immitis [coccidioidomycosis], and Blastomyces dermatitidis [blastomycosis]), and opportunistic organisms (e.g., Pneumocystis jirovecii), also produce infections of the lung. In turn, many of these infections produce significant morbidity and mortality.

The Common Cold

The common cold is a viral infection of the upper respiratory tract. It occurs more frequently than any other respiratory tract infection. Most adults have two to three colds per year, whereas the average school child may have up to 6 to 8 per year.

**Etiology and Pathogenesis**

Initially thought to be caused by either a single “cold virus” or a group of them, the common cold is now recognized to be associated with a number of viruses. The rhinoviruses are the most common cause of colds. Other viral causes include parainfluenza viruses, respiratory syncytial virus (RSV), human metapneumovirus (hMPV), coronaviruses, and adenoviruses. In children a new virus, bocavirus, causes respiratory tract infections. The season of the year and the person’s age, immunological state, and prior exposure are important factors in identifying the type of virus causing the infection and the type of symptoms that occur. For example, outbreaks of colds due to rhinoviruses are most common in early fall and late spring. Colds due to RSV peak in the winter and spring months, and infections due to the adenoviruses and coronaviruses are more frequent during the winter and spring months. Infections resulting from the RSV and parainfluenza viruses are most common and severe in children younger than 3 years of age. Infections occur less frequently and with milder symptoms with increasing age until after 65 years of age. Parainfluenza viruses often produce lower respiratory symptoms with first infections, but less severe upper respiratory symptoms with reinfections.

The “cold viruses” are spread rapidly from person to person. Children are the major reservoir of cold viruses, often acquiring a new virus from another child in school or day care. The fingers are the greatest source of spread, and the nasal mucosa and conjunctival surface of the eyes are the most common portals for entry of the virus. The most highly contagious period is during the first 3 days after the onset of symptoms, and the incubation period is approximately 5 days. Aerosol spread of colds through coughing and sneezing is much less important than the spread through direct mucous membrane contact by fingers picking up the virus from contaminated surfaces and carrying it to the nasal membranes and eyes.

**Clinical Manifestations**

The condition usually begins with a feeling of dryness and stuffiness affecting mainly the nasopharynx. This is followed by excessive production of nasal secretions and tearing of the eyes, which is often referred to as rhinitis. Usually, the secretions remain clear and watery. The mucous membranes of the upper respiratory tract become reddened and swollen. Often there is postnasal dripping (PND), which irritates the pharynx and larynx, causing sore throat and hoarseness. The affected person may experience headache and generalized malaise. In severe cases, there may be chills, fever, and exhaustion. The disease process is usually self-limited and lasts approximately 5 to 6 days. However, respiratory viruses account for approximately 40% to 75% of cases of acute otitis media in children.
Treatment

The common cold is an acute and self-limited illness in people who are otherwise healthy. Therefore, symptomatic treatment with rest and antipyretic drugs is usually all that is needed. Antibiotics are ineffective against viral infections and are not recommended. Many over-the-counter (OTC) remedies are available for treating the common cold. Antihistamines are popular OTC drugs because of their action in drying nasal secretions. However, they may dry up bronchial secretions and worsen the cough, and they may cause dizziness, drowsiness, and impaired judgment. If these drugs are used too frequently over too many days, they can cause rebound symptoms. In addition, there is no evidence that they shorten the duration of the cold. Decongestant drugs (i.e., sympathomimetic agents) are available in OTC nasal sprays, drops, and oral cold medications. These drugs constrict the blood vessels in the swollen nasal mucosa and reduce nasal swelling. Rebound nasal swelling can occur with indiscriminate use of nasal drops and sprays. Oral preparations containing decongestants may cause systemic vasoconstriction and elevation of blood pressure when given in doses large enough to relieve nasal congestion. Thus, people with hypertension, heart disease, hyperthyroidism, diabetes mellitus, or other health problems should avoid taking these drugs.

There is controversy regarding the use of vitamin C to reduce the incidence and severity of colds and influenza. Some studies have found vitamin C intake to be beneficial, and others have found it to be of questionable value in decreasing the severity of a common cold.

Rhinosinusitis

Rhinitis refers to inflammation of the nasal passages and sinusitis as inflammation of the paranasal sinuses. Although it has not been universally accepted, the suggestion has been made that the term rhinosinusitis is a more accurate term for what is commonly referred to as sinusitis. This is based on two key facts: the mucosa of the nasal cavities and paranasal sinuses is lined with a continuous mucous membrane layer, and viral upper respiratory tract infections frequently precede or occur along with sinus infections.

The paranasal sinuses are air sacs that develop during embryogenesis from a series of ridges and furrows within the cartilaginous capsule surrounding the developing nasal cavity. As development progresses, outpouchings from these furrows become lined with ciliated respiratory epithelium and invade the surrounding facial bones to become the major sinuses. Each sinus remains in constant communication with the nasal cavity through narrow openings or ostia. The sinuses are named for the bone in which they are located—frontal, ethmoid, maxillary, and sphenoidal (Fig. 36.1A). The frontal sinuses open into the middle meatus of the nasal cavity. The ethmoid sinuses consist of 3 to 15 air cells on each side of the ethmoid, with each maintaining a separate path to the nasal chamber. The anterior ethmoid, frontal, and maxillary sinuses all drain into the nasal cavity through a narrow passage called the ostiomeatal complex (see Fig. 36.1B). Because of this anatomic configuration, any defects in the anterior ethmoid sinus can obstruct the ostiomeatal complex and cause secondary disease of the frontal or maxillary sinuses. The maxillary sinuses are located inferior to the bony orbit and superior to the hard palate, and their openings are located superiorly and medially in the sinus, a location that impedes
drainage. The *sphenoidal sinuses* are located just anterior to the pituitary fossa behind the posterior ethmoid sinuses, with their openings draining into the sphenoid sinus recess at the top of the nasal cavity (see Fig. 36.1C).

Each sinus is lined with a mucosal surface that is continuous with that of the nasal passages. An active mucociliary clearance mechanism helps move fluid and microorganisms out of the sinuses and into the nasal cavity. Mucociliary clearance, along with innate and adaptive immune mechanisms, helps to keep the sinuses sterile. The lower oxygen content in the sinuses facilitates the growth of organisms, impairs local defenses, and alters the function of immune cells.

**Etiology and Pathogenesis**

The most common causes of rhinosinusitis are conditions that obstruct the narrow ostia that drain the sinuses. There are greater than 110 different antigenic serotypes, so it is quite possible to keep reinfecting oneself after a common cold virus. Most commonly, rhinosinusitis develops when a viral upper respiratory tract infection or allergic rhinitis, which causes mucosal swelling, obstructs the ostia and impairs the mucociliary clearance mechanism. Nasal polyps also can obstruct the sinus openings and facilitate sinus infection. Infections associated with nasal polyps can be self-perpetuating because constant irritation from the infection can facilitate polyp growth. Barotrauma caused by changes in barometric pressure, as occurs in airline pilots and flight attendants, may lead to impaired sinus ventilation and clearance of secretions. Swimming, diving, and abuse of nasal decongestants are other causes of sinus irritation and impaired drainage.

Rhinocesinusitis can be classified as acute, subacute, or chronic. Acute rhinosinusitis may be of viral, bacterial, or mixed viral–bacterial origin and may last from 5 to 7 days in the case of acute viral rhinosinusitis and up to 4 weeks in the case of acute bacterial rhinosinusitis. Recurrent acute rhinosinusitis is defined as four or more episodes of acute disease within a 12-month period. Subacute rhinosinusitis lasts from 4 weeks to less than 12 weeks, whereas chronic rhinosinusitis lasts beyond 12 weeks. Acute bacterial rhinosinusitis most commonly results from infection with *Haemophilus influenzae* or *Streptococcus pneumoniae*.

In chronic rhinosinusitis, anaerobic organisms, including species of *Peptostreptococcus, Fusobacterium, and Prevotella*, tend to predominate, alone or in combination with aerobes such as the *Streptococcus* species or *Staphylococcus aureus*. People with chronic rhinosinusitis and otitis media and effusion have been found to have accumulation of *Pseudomonas aeruginosa*, which forms biofilm in various ear, nose, and throat areas. This finding of the presence of biofilms with chronic ear, nose, and throat infections lends support to signs and symptoms caused by the chronic inflammation related to chronic otitis, rhinosinusitis, and effusion. In people who are immunocompromised (e.g., people with human immunodeficiency virus [HIV] infection), the sinuses may become infected with gram-negative species and opportunistic fungi. In this group, particularly those with prolonged neutropenia as a result of chemotherapy, the disease may have a fulminating and even fatal course.

**Clinical Manifestations**

The symptoms of acute viral rhinosinusitis often are difficult to differentiate from those of the common cold and allergic rhinitis. They include facial pain, headache, purulent nasal discharge, decreased sense of smell, and fever. A history of a preceding common cold and the presence of purulent nasal drainage, pain on bending, unilateral maxillary pain, and pain in the teeth are common with involvement of the maxillary sinuses. The symptoms of acute viral rhinosinusitis usually resolve within 5 to 7 days without medical treatment. Acute bacterial rhinosinusitis is suggested by symptoms that worsen after 5 to 7 days or persist beyond 10 days, or symptoms that are out of proportion to those usually associated with a viral upper respiratory tract infection. People who are immunocompromised, such as those with leukemia, aplastic anemia, bone marrow transplant, or HIV infection, often present with fever of unknown origin, rhinorrhea, or facial edema. Often, other signs of inflammation such as purulent drainage are absent.

In people with chronic rhinosinusitis, the only symptoms may be those such as nasal obstruction, a sense of fullness in the ears, postnasal drip, hoarseness, chronic cough, loss of taste and smell, or unpleasant breath. These symptoms are often felt to be more the result of the mediators, such as histamine, bradykinin, prostaglandin, or interleukin, than the virus itself. Sinus pain often is absent. Instead, the person may complain of a headache that is dull and constant. People with chronic rhinosinusitis may have superimposed bouts of acute rhinosinusitis. The epithelial changes that occur during acute and subacute forms of rhinosinusitis usually are reversible, but the mucosal changes that occur with chronic rhinosinusitis often are irreversible.

**Diagnosis and Treatment**

The diagnosis of rhinosinusitis usually is based on symptom history and a physical examination that includes inspection of the nose and throat. Headache due to sinusitis needs to be differentiated from other types of headache. Bending forward, coughing, or sneezing usually exaggerates sinusitis headache. Physical examination findings in acute bacterial sinusitis include turbinate edema, nasal crusts, and purulence of the nasal cavity. Sinus radiographs and computed tomography (CT) scans may be used. CT scans usually are reserved for diagnosis of chronic rhinosinusitis or to exclude complications. Magnetic resonance imaging (MRI) is usually reserved for cases of suspected neoplasms, long-standing chronic sinusitis, or fungal sinusitis.

Treatment of rhinosinusitis depends on the cause and includes appropriate use of antibiotics, mucolytic agents, and symptom relief measures. About two thirds of people with acute bacterial rhinosinusitis improve without antibiotic treatment. Most people with viral upper respiratory infections improve within 7 days. Therefore, treatment with antibiotics is usually reserved for persons who have had symptoms for more than 7 days and who present with two or more manifestations of acute bacterial rhinosinusitis (*i.e.*, purulent nasal drainage;
maxillary, tooth, or facial pain [especially if it is unilateral]; unilateral maxillary tenderness; or worsening of symptoms after initial improvement), or for those with severe symptoms.7 In addition to antibiotic therapy, the treatment of acute rhinosinusitis includes measures to promote adequate drainage by reducing nasal congestion. Oral and topical decongestants may be used for this purpose. The use of intranasal decongestants should be limited to 3 to 5 days to prevent rebound vasodilation. Antihistamines tend to dry up secretions and are not recommended as adjunctive treatment in acute viral or bacterial rhinosinusitis. Mucolytic agents such as guaifenesin may be used to thin secretions. Topical corticosteroids may be used to decrease inflammation in persons with allergic rhinitis or rhinosinusitis. Nonpharmacologic measures include saline nasal sprays, nasal irrigation, and mist humidification. However, although no studies have been conducted, most providers feel these nasal sprays and irrigations are not effective.

Surgical intervention directed at correcting obstruction of the ostiomeatal openings may be indicated in people with chronic rhinosinusitis that is resistant to other forms of therapy. Indications for surgical intervention include obstructive nasal polyps and obstructive nasal deformities.

Complications

Because of the sinuses’ proximity to the brain and orbital wall, sinusitis can lead to intracranial and orbital wall complications. Intracranial complications are seen most commonly with infection of the frontal and ethmoid sinuses because of their proximity to the dura and drainage of the veins from the frontal sinus into the dural sinus. Orbital complications can range from edema of the eyelids to orbital cellulitis and subperiosteal abscess formation. Facial swelling over the involved sinus, abnormal extraocular movements, protrusion of the eyeball, periorbital edema, or changes in mental status may indicate intracranial complications and require immediate medical attention.6

Influenza

Influenza is one of the most important causes of acute upper respiratory tract infection in humans. In the United States about 10% to 20% of people are diagnosed with influenza every year, and approximately 20,000 die.13 Rates of infection are highest among children and older adults, but rates of serious illness and death are highest among people 65 years of age or older.11

The viruses that cause influenza belong to the Orthomyxoviridae family, whose members are characterized by a segmented, single-stranded ribonucleic acid (RNA) genome.13 There are three types of influenza viruses that cause epidemics in humans: types A, B, and C. Influenza A differs in its ability to infect multiple species, including avian and mammalian species. The influenza A virus is further divided into subtypes based on two surface glycoproteins: hemagglutinin (HA) and neuraminidase (NA).13 HA is an attachment protein that allows the virus to enter epithelial cells in the respiratory tract, and NA facilitates viral replication from the cell.13 Contagion results from the ability of the influenza A virus to develop new HA and NA subtypes against which the population is not protected. An antigenic shift, which involves a major genetic rearrangement in either antigen, may lead to epidemic or pandemic infection. Lesser changes, called antigenic drift, find the population partially protected by cross-reacting antibodies. Influenza B and C undergo less frequent antigenic shifts than influenza A, probably because few related viruses exist in mammalian or avian species.13

As with many viral respiratory tract infections, influenza is more contagious than bacterial respiratory tract infections. In contrast to the rhinoviruses, transmission occurs by inhalation of droplet nuclei rather than touching contaminated objects. Most infected people develop symptoms of the disease, increasing the likelihood of contagion through spread of infectious droplets. Young children are most likely to become infected and also to spread the infection. The incubation period for influenza is 1 to 5 days, with 2 days being the average. People become infectious starting 1 day before their symptoms begin and remain infectious through approximately 5 days after illness onset.13 Virus shedding can continue for approximately 3 weeks.

Pathogenesis

The influenza viruses can cause three types of infections: an uncomplicated upper respiratory infection (rhinotracheitis), viral pneumonia, and a respiratory viral infection followed by a bacterial infection. Influenza initially establishes upper airway infection. In doing this, the virus first targets and kills mucus-secreting, ciliated, and other epithelial cells, leaving gaping holes between the underlying basal cells and allowing extracellular fluid to escape. This is the reason for the “runny nose” that is characteristic of this phase of the infection. If the virus spreads to the lower respiratory tract, the infection can cause severe shedding of bronchial and alveolar cells down to a single-cell-thick basal layer. Additionally, compromising the natural defenses of the respiratory tract, influenza infection promotes bacterial adhesion to epithelial cells. Pneumonia may result from a viral pathogenesis or from a secondary bacterial infection.

Clinical Manifestations

In the early stages, the symptoms of influenza often are indistinguishable from other viral infections. There is an abrupt onset of fever and chills, malaise, muscle aching, headache, profuse, watery nasal discharge, nonproductive cough, and sore throat.13 One distinguishing feature of an influenza viral infection is the rapid onset, sometimes in as little as 1 to 2 minutes, of profound malaise. The symptoms of uncomplicated rhinotracheitis usually peak by days 3 to 5 and disappear by days 7 to 10. The aforementioned symptoms can be caused by any of the influenza A or B viruses. Influenza C virus infection causes symptoms similar to the common cold.

Viral pneumonia occurs as a complication of influenza, most frequently in older adults or in people with cardiopulmonary disease. However, it has been reported in pregnant women and in healthy, immunocompetent people. It typically develops within 1 day after onset of influenza and is characterized by rapid
progression of fever, tachypnea, tachycardia, and hypotension. The clinical course of influenza pneumonia progresses rapidly. It can cause hypoxemia and death within a few days of onset. Survivors often develop diffuse pulmonary fibrosis.

Secondary complications typically include sinusitis, otitis media, bronchitis, and bacterial pneumonia. People in whom secondary bacterial pneumonia develops usually report that they were beginning to feel better when they experienced a return of fever, shaking chills, pleuritic chest pain, and productive cough. The most common causes of secondary bacterial pneumonia are *S. pneumoniae*, *S. aureus*, *H. influenzae*, and *Moraxella catarrhalis*. This form of pneumonia commonly produces less tachypnea and is usually milder than primary influenza pneumonia. Influenza-related deaths can result from pneumonia as well as exacerbations of cardiopulmonary conditions and other disease. Reye syndrome (fatty liver with encephalitis) is a rare complication of influenza, particularly in young children who have been given aspirin as an antipyretic agent.

**Diagnosis and Treatment**

The appropriate treatment of people with influenza depends on accurate and timely diagnosis. Early diagnosis can reduce the inappropriate use of antibiotics and provide the opportunity for use of an antiviral drug. Rapid diagnostic tests, which are available for use in outpatient settings, allow health care providers to diagnose influenza more accurately, consider treatment options more carefully, and monitor the influenza type and its prevalence in their community.

The goals of treatment for influenza are designed to limit the infection to the upper respiratory tract. The symptomatic approach for treatment of uncomplicated influenza rhinotracheitis focuses on rest, keeping warm, managing the fever, and keeping well hydrated. Analgesics and cough medications can also be used. Rest decreases the oxygen requirements of the body and reduces the respiratory rate and the chance of spreading the virus from the upper to lower respiratory tract. Keeping warm helps maintain the respiratory epithelium at a core body temperature of 37°C (or higher if fever is present), thereby inhibiting viral replication, which is optimal at 35°C. Drinking large amounts of liquids ensures that the function of the epithelial lining of the respiratory tract is not further compromised by dehydration. Antiviral medications may be indicated in some people. Antibacterial antibiotics should be reserved for bacterial complications.

Four antiviral drugs are available for treatment of influenza: Symmetrel (amantadine), Flumadine (rimantadine), Relenza (zanamivir), and Tamiflu (oseltamivir). The first-generation antiviral drugs amantadine and rimantadine are similarly effective against influenza A but not influenza B. These agents inhibit the uncoating of viral RNA in the host cells and prevent its replication. Both drugs are effective in prevention of influenza A in high-risk groups and in treatment of people who acquire the disease. Unfortunately, resistance to the drugs develops rapidly, and strains that are resistant to amantadine also are resistant to rimantadine. Amantadine stimulates release of catecholamines, which can produce central nervous system side effects such as anxiety, depression, and insomnia. The second-generation antiviral drugs zanamivir and oseltamivir are inhibitors of NA, a viral glycoprotein that is necessary for viral replication and release. These drugs, which have been approved for treatment of acute uncomplicated influenza infection, are effective against both influenza A and B viruses. Zanamivir and oseltamivir result in less resistance than amantadine and rimantadine. Zanamivir is administered intranasally, and oseltamivir is administered orally. Zanamivir can cause bronchospasm and is not recommended for people with asthma or chronic obstructive lung disease. To be effective, the antiviral drugs should be initiated within 48 hours after onset of symptoms.

**Influenza Immunization**

Because influenza is so highly contagious, prevention relies primarily on vaccination. The formulation of the vaccines must be changed yearly in response to antigenic changes in the influenza virus. The Centers for Disease Control and Prevention (CDC) Advisory Committee on Immunization Practices (ACIP) annually updates its recommendations for the composition of the vaccine. Influenza vaccines are contraindicated in people with anaphylactic hypersensitivity to eggs or to other components of the vaccine, people with a history Guillain-Barré syndrome, and people with acute febrile illness.

The effectiveness of the influenza vaccine in preventing and lessening the effects of influenza infection depends primarily on the age and immunocompetence of the recipient and the match between the virus strains included in the vaccine and those that circulate during the influenza season. When there is a good match, the vaccine is effective in preventing the illness in approximately 70% to 90% of healthy people younger than 65 years of age. Fluzone High-Dose is a new influenza vaccine for seniors older than 65 years.

All people 6 months of age and older in the United States are recommended to receive the annual influenza vaccine. In addition, the ACIP recommends an annual vaccine specifically for the following new high-risk populations vulnerable for serious influenza-related complications: people with BMI rates greater than 40, Alaskan Natives, and American Indians.

**Avian Influenza (Bird Flu)**

Avian influenza, or “bird flu,” is an infection caused by avian influenza viruses. The normal hosts for avian influenza viruses are birds and occasionally pigs. These influenza viruses occur naturally among birds. Wild birds carry the viruses in their intestines, but usually are not affected by them. However, the virus is highly contagious among avian species and can infect and kill domestic poultry, such as chickens, ducks, and turkeys. Infected birds shed the virus in their saliva, nasal secretions, and feces. Susceptible birds become infected when they have contact with contaminated secretions or feces. Avian strains of the influenza virus do not usually cause outbreaks of disease in humans unless a reassortment of the virus genome has occurred within an intermediate mammalian host such as a pig. In this setting, a virus is produced that contains mammalian characteristics as well as avian characteristics to which humans may not
be immune. It is noteworthy that many of the pandemics of the past were thought to arise in Asia, where large human populations live in close proximity to ducks, chickens, and pigs, thus facilitating the phenomenon of viral reassortment.17

Recently, a highly pathogenic influenza A subtype, H5N1, was found in poultry in East and Southeast Asian countries.17 Although the H5N1 strain is highly contagious from one bird to another, its transmission from human to human is relatively inefficient and not sustained. The result is only rare cases of person-to-person transmission. Most cases occur after exposure to infected poultry or surfaces contaminated with poultry droppings. Because infection in humans is associated with a high mortality rate, there is considerable concern that the H5N1 strain might mutate and initiate a pandemic. People who contract avian flu generally complain about typical influenza symptoms along with eye infections, pneumonia, and acute RDS.17

There currently is no commercially available vaccine to protect humans against the bird flu. Current commercial rapid diagnostic tests are not optimally sensitive or specific for detection of the virus. Most Asian H5N1 influenza strains are resistant to amantadine and rimantadine. The NA inhibitors, oseltamivir (Tamiflu) and zanamivir (Relenza), would probably be effective if administered within 48 hours, but additional studies are needed to demonstrate their effectiveness.

Swine Flu (H1N1)
In June 2009, the World Health Organization identified a world influenza pandemic. This pandemic was caused by an influenza A flu known as the swine-origin influenza A flu (H1N1). H1N1 caused extremely high fevers and was especially serious in young adults less than 25 years of age. Interestingly, older adults were not at higher risk for H1N1 as they tend to be for most infections such as seasonal influenza. This virus is spread from human to human and is generally referred to as the swine flu. The majority of people affected by the virus did not experience severe illness although there were some who needed hospitalization and who even died. The CDC does recommend that most people be vaccinated against H1N1.

Pneumonias
The term pneumonia describes inflammation of parenchymal structures of the lung in the lower respiratory tract, such as the alveoli and the bronchioles. An estimated 4 to 10 million cases occur annually in the United States.9 Pneumonia is the sixth leading cause of death in the United States and the most common cause of death from infectious disease.6 Etiologic agents include infectious and noninfectious agents. Inhalation of irritating fumes or aspiration of gastric contents, although much less common than infectious causes, can result in severe pneumonia.

Although antibiotics have significantly reduced the mortality rate from pneumonias, these diseases remain an important immediate cause of death among older adults and in people with debilitating diseases.18 There have been subtle changes in the spectrum of microorganisms that cause infectious pneumonias, including a decrease in pneumonias caused by S. pneumoniae and an increase in pneumonias caused by other microorganisms such as Pseudomonas, Candida and other fungi, and nonspecific viruses. Many of these pneumonias occur in people with impaired immune defenses, including those on immunosuppressant drugs to prevent organ transplant or bone marrow rejection, or in people who frequently take anti-inflammatory drugs.

Because of the overlap in symptomatology and changing spectrum of infectious organisms involved, pneumonias are increasingly being classified according to the setting (community or hospital in which it occurs). Using this classification, pneumonias can be community-acquired and hospital-acquired (nosocomial) pneumonias.6 People with compromised immune function constitute a special concern in both categories.

Pneumonias can also be classified according to the type of agent (typical or atypical) causing the infection, and distribution of the infection (lobar pneumonia or bronchopneumonia). Typical pneumonias result from infection by bacteria that multiply extracellularly in the alveoli and cause inflammation and exudation of fluid into the air-filled spaces of the alveoli (Fig. 36.2). Atypical pneumonias are caused by viral and mycoplasma infections that involve the alveolar septum and the interstitium of the lung. They produce less striking symptoms and physical findings than bacterial pneumonia. For example, there is a lack of alveolar infiltration and purulent sputum, leukocytosis, and lobar consolidation on the chest imaging.

FIGURE 36.2 • Location of inflammatory processes in (A) typical and (B) atypical forms of pneumonia.
KEY POINTS

PNEUMONIAS

- Pneumonias are respiratory disorders involving inflammation of the lung structures, such as the alveoli and bronchioles.
- Pneumonias due to infectious agents commonly are classified according to the source of infection (community- vs. hospital-acquired) and according to the immune status of the host (pneumonia in the immunocompromised person).

Community-Acquired Pneumonia

The term community-acquired pneumonia is used to describe infections from organisms found in the community rather than in the hospital or nursing home. It is defined as an infection that begins outside the hospital or is diagnosed within 48 hours after admission to the hospital in a person who has not resided in a long-term care facility for 14 days or more before admission. Community-acquired pneumonia may be further categorized according to risk of mortality and need for hospitalization based on age, presence of coexisting disease, and severity of illness, using physical examination, laboratory, and radiologic findings.

Community-acquired pneumonia may be either bacterial or viral. The most common cause of infection in all categories is *S. pneumoniae*. Other common pathogens include *H. influenzae*, *S. aureus*, and gram-negative bacilli. Less common agents, although they are becoming more common, are *Mycoplasma pneumoniae, Legionella, Chlamydia* species, and viruses, sometimes called atypical agents. Common viral causes of community-acquired pneumonia include the influenza virus, RSV, adenovirus, and parainfluenza virus.

The methods used in the diagnosis of community-acquired pneumonia depend on age, coexisting health problems, and the severity of illness. In people younger than 65 years of age and without coexisting disease, diagnosis is usually based on history and physical examination, chest radiographs, and knowledge of the microorganisms currently causing infections in the community. Sputum specimens may be obtained for staining procedures and culture. Blood cultures may be done for people requiring hospitalization.

Treatment involves the use of appropriate antibiotic therapy. Empiric antibiotic therapy, based on knowledge regarding an antibiotic’s spectrum of action and ability to penetrate bronchopulmonary secretions, often is used for people with community-acquired pneumonia who do not require hospitalization. Hospitalization and more intensive care may be required depending on the person’s age, preexisting health status, and severity of the infection.

Hospital-Acquired Pneumonia

Hospital-acquired pneumonia is defined as a lower respiratory tract infection that was not present or incubating on admission to the hospital. Usually, infections occurring 48 hours
or more after admission are considered hospital acquired. Hospital-acquired pneumonia is the second most common cause of hospital-acquired infection and has a mortality rate of 20% to 50%. People requiring intubation and mechanical ventilation are particularly at risk. Others at risk include those with compromised immune function, chronic lung disease, and airway instrumentation, such as endotracheal intubation or tracheotomy.

Most hospital-acquired infections are bacterial. The organisms are those present in the hospital environment and include *P. aeruginosa*, *S. aureus*, *Enterobacter* species, *Klebsiella* species, *Escherichia coli*, and *Serratia* species. The organisms that are responsible for hospital-acquired pneumonias are different from those responsible for community-acquired pneumonias, and many of them have acquired antibiotic resistance and are more difficult to treat.

**Pneumonia in Immunocompromised People**

Pneumonia in immunocompromised people remains a major source of morbidity and mortality. The term *immunosuppressed host* usually is applied to people with a variety of underlying defects in host defenses. It includes people with primary and acquired immunodeficiency states, those who have undergone bone marrow or organ transplantation, people with solid organ or hematologic cancers, and those on corticosteroid and other immunosuppressant drugs.

Although almost all types of microorganisms can cause pulmonary infection in immunocompromised people, certain types of immunologic defects tend to favor certain types of infections. Defects in humoral immunity predispose to bacterial infections against which antibodies play an important role, whereas defects in cellular immunity predispose to infections caused by viruses, fungi, mycobacteria, and protozoa. Neutropenia and impaired granulocyte function, as occur in people with leukemia, chemotherapy, and bone marrow depression, predispose to infections caused by *S. aureus*, *Aspergillus*, gram-negative bacilli, and *Candida*. The time course of infection often provides a hint to the type of agent involved. A fulminant pneumonia usually is caused by bacterial infection, whereas an insidious onset usually is indicative of a viral, fungal, protozoal, or mycobacterial infection.

**Acute Bacterial (Typical) Pneumonias**

Bacterial pneumonias remain an important cause of mortality among older adults and people with debilitating illnesses. The lung below the main bronchi is normally sterile despite frequent entry of microorganisms into the air passages by inhalation during ventilation or aspiration of nasopharyngeal secretions. Most people unknowingly aspirate small amounts of organisms that have colonized their upper airways, particularly during sleep. These organisms do not normally cause infection because of the small numbers that are aspirated and because of the respiratory tract’s defense mechanisms that prevent them from entering the distal air passages (Table 36.1). Loss of the cough reflex, damage to the ciliated epithelium that lines the respiratory tract, or impaired immune defenses predispose to colonization and infection of the lower respiratory system. Bacterial adherence also plays a role in colonization of the lower airways. The epithelial cells of critically and chronically ill people are more receptive to binding microorganisms that cause pneumonia. Other clinical risk factors favoring colonization of the tracheobronchial tree include antibiotic therapy that alters the normal bacterial flora, diabetes, smoking, chronic bronchitis, and viral infection.

Bacterial pneumonias are commonly classified according to etiologic agent. This is because the clinical and morphologic features, and thus the therapeutic implications, often vary with the causative agent. The discussion in this section focuses on two types of bacterial pneumonia: pneumococcal pneumonia and Legionnaire disease.

**Pneumococcal Pneumonia.** *Streptococcus pneumoniae* (pneumococcus) remains the most common cause of bacterial pneumonia. *S. pneumoniae* is a gram-positive diplococcus, possessing a capsule of polysaccharide. The virulence of the pneumococcus is a function of its capsule, which prevents or delays digestion by phagocytes. The polysaccharide

is an antigen that primarily elicits a B cell response with antibody production. In the absence of antibody, clearance of the pneumococci from the body relies on the reticuloendothelial system, with the macrophages in the spleen playing a major role in elimination of the organism. This, along with the spleen’s role in antibody production, increases the risk for pneumococcal bacteremia in people who are anatomically or functionally asplenic, such as children with sickle cell disease. The initial step in the pathogenesis of pneumococcal infection is the attachment and colonization of the organism to the mucus and cells of the nasopharynx. Colonization does not equate with signs of infection. Perfectly healthy people can be colonized and carry the organism without evidence of infection. Healthy colonized people largely spread particular strains of pneumococci, particularly antibiotic-resistant strains.

The pathologic process of pneumococcal pneumonia can be divided into the four stages—edema, red hepatization, gray hepatization, and resolution (see Fig. 36.5).

During the first stage of pneumococcal pneumonia, the alveoli become filled with a protein-rich edema fluid containing numerous organisms (Fig. 36.6). Marked capillary congestion follows, leading to massive outpouring of polymorphonuclear leukocytes and red blood cells. Because the first consistency of the affected lung resembles that of the liver, this stage is referred to as the red hepatization stage. The next stage, occurring after 2 or more days, depending on the success of treatment, involves the arrival of macrophages that phagocytose the fragmented polymorphonuclear cells, red blood cells, and other cellular debris. During this stage, which is termed the gray hepatization stage, the congestion...
has diminished but the lung is still firm. The alveolar exudate is then removed and the lung gradually returns to normal.

The signs and symptoms of pneumococcal pneumonia vary widely, depending on the age and health status of the infected person. In previously healthy people, the onset usually is sudden and is characterized by malaise, severe, shaking chills, and fever. During the initial or congestive stage, coughing brings up watery sputum and breath sounds are limited, with fine crackles. As the disease progresses, the character of the sputum changes; it may be blood tinged or rust colored to purulent. Pleuritic pain, a sharp pain that is more severe with respiratory movements, is common. With antibiotic therapy, fever usually subsides in approximately 48 to 72 hours, and recovery is uneventful. Older adults are less likely to experience marked elevations in temperature. In fact, the only sign of pneumonia may be a loss of appetite and deterioration in mental status in older adults.

Treatment includes the use of antibiotics that are effective against S. pneumoniae. In the past, S. pneumoniae was uniformly susceptible to penicillin. However, penicillin-resistant and multidrug-resistant strains have been emerging in the United States and other countries. Pneumococcal pneumonia can be prevented through immunization. The capsular polysaccharides induce antibodies primarily by T cell–independent mechanisms. The vaccine is recommended for people 65 years of age or older and persons aged 2 to 65 years with chronic illnesses, particularly cardiovascular and pulmonary diseases, diabetes mellitus, and alcoholism, who sustain increased morbidity with respiratory infections. Immunization also is recommended for immunocompromised people 2 years of age or older, including those with sickle cell disease, splenectomy, Hodgkin disease, multiple myeloma, renal failure, nephrotic syndrome, organ transplantation, and HIV infection. Immunization is also recommended for residents in special environments or social settings in which the risk for invasive pneumococcal disease is increased (e.g., Alaskan Natives, certain Native American populations) and for residents of nursing homes and long-term care facilities.

Because their immune system is immature, the antibody response to most pneumococcal capsular polysaccharides usually is poor or inconsistent in children younger than 2 years of age. With the success of H. influenzae type B vaccine, S. pneumoniae has become the leading cause of bacterial meningitis in the United States. S. pneumoniae also contributes substantially to noninvasive respiratory infections and is the most common cause of community-acquired pneumonia, acute otitis media, and sinusitis among young children.

**Legionnaire Disease.** Legionnaire disease is a form of bronchopneumonia caused by a gram-negative rod, Legionella pneumophila. Transmission from person to person has not been documented, and infection normally occurs by acquiring the organism from the environment. Infection typically occurs when water that contains the pathogen is aerosolized into appropriately sized droplets and is inhaled or aspirated by a susceptible host. The disease was first recognized and received its name after an epidemic of severe and, for some, fatal pneumonia that developed among delegates to the 1976 American Legion convention held in a Philadelphia hotel. The spread of infection was traced to a water-cooled air-conditioning system. Although healthy people can contract the infection, the risk is greatest among smokers, persons with chronic diseases, and those with impaired cell-mediated immunity.

Symptoms of the disease typically begin approximately 2 to 10 days after infection. Onset is usually abrupt, with malaise, weakness, lethargy, fever, and dry cough. Other manifestations include disturbances of central nervous system function, gastrointestinal tract involvement, arthralgias, and elevation in body temperature. The presence of pneumonia along with diarrhea, hyponatremia, and confusion is characteristic of Legionella pneumonia. The disease causes consolidation of lung tissues and impairs gas exchange.

Diagnosis is based on clinical manifestations, radiologic studies, and specialized laboratory tests to detect the presence of the organism. Of these, the Legionella urinary antigen test is a relatively inexpensive, rapid test that detects antigens of L. pneumophila in the urine. The urine test usually is easier to obtain because people with legionellosis often have a nonproductive cough, and the test results remain positive for weeks despite antibiotic therapy. The test is available as both a radioimmunoassay and an enzyme immunoassay.

Treatment consists of administration of antibiotics that are known to be effective against L. pneumophila. Delay in instituting antibiotic therapy significantly increases mortality rates; therefore, antibiotics known to be effective against L. pneumophila should be included in the treatment regimen for severe community-acquired pneumonia.

**Primary Atypical Pneumonia**

The primary atypical pneumonias are caused by a variety of agents, the most common being Mycoplasma pneumoniae. Mycoplasma infections are particularly common among children and young adults. Other etiologic agents include viruses (e.g., influenza virus, RSVs, adenoviruses, rhinoviruses, and rubeola [measles], and varicella [chickenpox] viruses) and Chlamydia pneumoniae. In some cases, the cause is unknown.

The atypical pneumonias are characterized by patchy involvement of the lung, largely confined to the alveolar septum and pulmonary interstitium. The term atypical denotes a lack of lung consolidation, production of moderate amounts of sputum, moderate elevation of white blood cell count, and lack of alveolar exudate. The agents that cause atypical pneumonias damage the respiratory tract epithelium and impair respiratory tract defenses, thereby predisposing to secondary bacterial infections. The sporadic form of atypical pneumonia is usually mild with a low mortality rate. It may, however, assume epidemic proportions with intensified severity and greater mortality, as in the influenza pandemics of 1915 and 1918.

The clinical course among people with mycoplasmal and viral pneumonias varies widely from a mild infection (e.g., influenza types A and B, adenovirus) that masquerades as a chest cold to a more serious and even fatal outcome. The symptoms may remain confined to fever, headache, and muscle
aches and pains. Cough, when present, is characteristically dry, hacking, and nonproductive. The diagnosis is usually made based on history, physical findings, and chest x-rays. There are a few assessment tools to assist in determining treatment for people with pneumonia that also predict mortality such as the CURB 65.22

Tuberculosis

Tuberculosis is the world’s foremost cause of death from a single infectious agent. Approximately 2 billion people are infected globally.23 It is estimated that each year more than 9.4 million new cases of tuberculosis occur worldwide and approximately 2 million people are thought to be latently infected with *M. tuberculosis*.24 With the introduction of antibiotics in the 1950s, the United States and other Western countries enjoyed a long decline in the number of infections until the mid-1980s. Since that time, the rate of infection has increased, particularly among people infected with HIV. Tuberculosis is more common among foreign-born people from countries with a high incidence of tuberculosis and among residents of high-risk congregate settings such as correctional facilities, drug treatment facilities, and homeless shelters. Outbreaks of a drug-resistant form of tuberculosis have emerged, complicating the selection of drugs and affecting the duration of treatment.

Tuberculosis is an infectious disease caused by the mycobacterium, *M. tuberculosis*. The mycobacteria are slender, rod-shaped, aerobic bacteria that do not form spores. They are similar to other bacterial organisms except for an outer waxy capsule that makes them more resistant to destruction; the organism can persist in old necrotic and calcified lesions and remain capable of reinfecting growth. The waxy coat also causes the organism to retain red dye when treated with acid in acid-fast staining.23 Thus, the mycobacteria are often referred to as *acid-fast bacilli*. Although *M. tuberculosis* can infect practically any organ of the body, the lungs are most frequently involved. The tubercle bacilli are strict aerobes that thrive in an oxygen-rich environment. This explains their tendency to cause disease in the upper lobe or upper parts of the lower lobe of the lung, where the ventilation and oxygen content are greatest.

*Mycobacterium tuberculosis* hominis is the most frequent form of tuberculosis that threatens humans. Other mycobacteria, including Mycobacterium avium–intracellulare (MAI) complex, are much less virulent than *M. tuberculosis hominis*. These mycobacteria rarely cause disease except in severely immunosuppressed people, such as those with HIV infection. Generally, MAI complex is transmitted from eating contaminated food or water.

*Mycobacterium tuberculosis hominis* is an airborne infection spread by minute, invisible particles, called *droplet nuclei*, that are harbored in the respiratory secretions of people with active tuberculosis. Coughing, sneezing, and talking all create respiratory droplets. These droplets evaporate and leave organisms (droplet nuclei), which remain suspended in the air and are circulated by air currents. Thus, living under crowded and confined conditions increases the risk for spread of the disease.

### Key Points

**Tuberculosis**

- Tuberculosis is an infectious disease caused by *M. tuberculosis*, a rod-shaped, aerobic bacterium that is resistant to destruction and can persist in necrotic and calcified lesions for prolonged periods and remain capable of reinstating growth.
- A positive tuberculin skin test results from a cell-mediated immune response and implies that a person has been infected with *M. tuberculosis* and has mounted a cell-mediated immune response. It does not mean that the person has active tuberculosis.

**Pathogenesis**

The pathogenesis of tuberculosis in a previously unexposed immunocompetent person is centered on the development of a cell-mediated immune response that confers resistance to the organism and development of tissue hypersensitivity to the tubercular antigens.23 The destructive features of the disease, such as caseating necrosis and cavitation, result from the hypersensitivity immune response rather than the destructive capabilities of the tubercle bacillus. Macrophages are the primary cell infected with *M. tuberculosis*. Inhaled droplet nuclei pass down the bronchial tree without settling on the epithelium and are deposited in the alveoli. Soon after entering the lung, the bacilli are phagocytosed by alveolar macrophages but resist killing, apparently because cell wall lipids of *M. tuberculosis* block fusion of phagosomes and lysosomes. Although the macrophages that first ingest *M. tuberculosis* cannot kill the organisms, they initiate a cell-mediated immune response that eventually contains the infection. As the tubercle bacilli multiply, the infected macrophages degrade the mycobacteria and present their antigens to T lymphocytes. The sensitized T lymphocytes, in turn, stimulate the macrophages to increase their concentration of lytic enzymes and ability to kill the mycobacteria. When released, these lytic enzymes also damage lung tissue. The development of a population of activated T lymphocytes and related development of activated macrophages capable of ingesting and destroying the bacilli constitutes the cell-mediated immune response, a process that takes about 3 to 6 weeks to become effective.

In people with intact cell-mediated immunity, the cell-mediated immune response results in the development of a gray-white, circumscribed granulomatous lesion, called a *Ghon focus*, that contains the tubercle bacilli, modified macrophages, and other immune cells.23 It is usually located in the subpleural area of the upper segments of the lower lobes or in the lower segments of the upper lobe. When the number of organisms is high, the hypersensitivity reaction produces significant tissue necrosis, causing the central portion of the Ghon focus to undergo soft, caseous (cheeselike)
necrosis. During this same period, tubercle bacilli, free or inside macrophages, drain along the lymph channels to the tracheobronchial lymph nodes of the affected lung, and there evoke the formation of caseous granulomas. The combination of the primary lung lesion and lymph node granulomas is called a Ghon complex (Fig. 36.7). The Ghon complex eventually heals, undergoing shrinkage, fibrous scarring, and calcification, the latter visible radiographically. However, small numbers of organisms may remain viable for years. Later, if immune mechanisms decline or fail, latent tuberculosis infection has the potential to develop into secondary tuberculosis.

**Clinical Manifestations**

**Primary Tuberculosis.** Primary tuberculosis is a form of the disease that develops in previously unexposed and therefore unsensitized people. It typically is initiated as a result of inhaling droplet nuclei that contain the tubercle bacillus (Fig. 36.8). Most people with primary tuberculosis go on to develop latent infection in which T lymphocytes and macrophages surround the organism in granulomas that limit their spread. People with latent tuberculosis do not have active disease and cannot transmit the organism to others. In approximately 5% of newly infected people, the immune response is inadequate. These people go on to develop progressive primary tuberculosis with continued destruction of lung tissue and spread to multiple sites within the lung. People with HIV infection and others with disorders of cell-mediated immunity are more likely to develop progressive tuberculosis if they become infected. In those who develop progressive disease, the symptoms are usually insidious and nonspecific, with fever, weight loss, fatigue, and night sweats. Sometimes the onset of symptoms is abrupt, with high fever, pleuritis, and lymphadenitis. As the disease spreads, the organism gains access to the sputum, allowing the person to infect others.

In rare instances, tuberculosis may erode into a blood vessel, giving rise to hematogenic dissemination. *Miliary tuberculosis* describes minute lesions, resembling millet seeds, resulting from this type of dissemination that can involve almost any organ, particularly the brain, meninges, liver, kidney, and bone marrow.

**Primary Progressive Tuberculosis.** Primary progressive tuberculosis represents either reinfection from inhaled droplet nuclei or reactivation of a previously healed primary lesion (see Fig. 36.8). It often occurs in situations of impaired body defense mechanisms. The partial immunity that follows primary tuberculosis affords protection against reinfection and to some extent aids in localizing the disease should reactivation occur. In primary progressive tuberculosis, the cell-mediated hypersensitivity reaction can be an aggravating factor, as evidenced by the frequency of cavitation and bronchial dissemination. The cavities may coalesce to a size of up to 10 to 15 cm in diameter (Fig. 36.9). Pleural effusion and tuberculous empyema are common as the disease progresses.

People with early primary progressive tuberculosis commonly present with low-grade fevers, fatigue, and weight loss. A cough initially is dry but later becomes productive...
with purulent and sometimes blood-tinged sputum. Dyspnea and orthopnea develop as the disease advances to late primary progressive tuberculosis. Also night sweats, anemia, and rales on lung auscultation are evident as the disease progresses.\(^\text{23}\)

**Diagnosis**

Diagnosing TB has many challenges and is often missed, especially with people who present with less than classic symptoms of TB and who do not fit the most impacted TB population groups.\(^\text{26}\) The most frequently used screening methods for pulmonary tuberculosis are tuberculin skin tests and chest x-ray. The tuberculin skin test measures the delayed hypersensitivity (i.e., cell-mediated, type IV) that follows exposure to the tubercle bacillus. People who become tuberculin positive usually remain so for the remainder of their lives. A positive reaction to the skin test does not mean that a person has active tuberculosis. It only means that there has been exposure to the bacillus and that cell-mediated immunity to the organism has developed. False-positive and false-negative skin test reactions can occur. False-positive reactions can result from cross-reactions with nontuberculosis mycobacteria, such as *M. avium-intracellulare* complex (see Fig. 36.10). Because the hypersensitivity response to the tuberculin test depends on cell-mediated immunity, a false-negative test result can occur because of immunodeficiency states that result from HIV infection, immunosuppressive therapy, lymphoreticular malignancies, or aging. This is called *anergy*. In the immunocompromised person, a negative tuberculin test result can mean that the person has a true lack of exposure to tuberculosis or is unable to mount an immune response to the test. The QuantiFERON-TB Gold test (QFT-TB Gold) is used to detect active and latent TB by measuring interferon-y (IFN-y), which is part of the cell-mediated immune activity to TB response.\(^\text{23,25}\) It has a 24-hour test results turnaround, but it is expensive and is not available at all health care settings.

Definitive diagnosis of active pulmonary tuberculosis requires identification of the organism from cultures or identification of the organism from deoxyribonucleic acid (DNA) or RNA amplification techniques.\(^\text{23}\) Bacteriologic studies (i.e., acid-fast stain and cultures) of early sputum specimens, gastric aspirations, or bronchial washings obtained during fiberoptic bronchoscopy may be used.

**Treatment**

The goals of treatment are to eliminate all tubercle bacilli from an infected person while avoiding emergence of significant drug resistance. Treatment of active tuberculosis requires the use of multiple drugs.\(^\text{24}\) Tuberculosis is an unusual disease in that chemotherapy is required for a relatively long period. The tubercle bacillus is an aerobic organism that multiplies slowly and remains relatively dormant in oxygen-poor caseous material. It undergoes a high rate of mutation and tends to acquire resistance to any one drug. For this reason, multidrug regimens are used for treating people with active tuberculosis.\(^\text{24}\) Drug susceptibility tests are used to guide treatment in drug-resistant forms of the disease.

Two groups meet the criteria established for the use of antimycobacterial therapy for tuberculosis: people with active tuberculosis and people who have had contact with cases of...
active tuberculosis and who are at risk for development of an active form of the disease. Prophylactic treatment is used for people who are infected with *M. tuberculosis* but do not have active disease.24 This group includes the following:

- People with a positive skin test result who have had close contact with active cases of tuberculosis
- People who have converted from a negative to positive skin test result within 2 years
- People who have a history of untreated or inadequately treated tuberculosis
- People who have chest radiographs with evidence of tuberculosis but no bacteriologic evidence of the active disease
- People who have special risk factors such as silicosis, diabetes mellitus, prolonged corticosteroid therapy, immunosuppression therapy, end-stage renal disease, chronic malnutrition from any cause, or hematologic or reticuloendothelial cancers
- People who have a positive HIV test result or have AIDS
- People who are 35 years of age or younger with a positive reaction of unknown duration (these people are considered to harbor a small number of microorganisms and usually are treated with isoniazid [INH])

The primary drugs used in the treatment of tuberculosis are INH, rifampin, pyrazinamide (PZA), ethambutol, and streptomycin.24 INH is remarkably potent against the tubercle bacillus and probably is the most widely used drug for tuberculosis. Although its exact mechanism of action is unknown, it apparently combines with an enzyme that is needed by the INH-susceptible strains of the tubercle bacillus. Resistance to the drug develops rapidly, and combination with other effective drugs delays the development of resistance. Rifampin inhibits RNA synthesis in the bacillus. Although ethambutol and PZA are known to inhibit the growth of the tubercle bacillus, their mechanisms of action are largely unknown. Streptomycin, the first drug found to be effective against tuberculosis, must be given by injection, which limits its usefulness, particularly in long-term therapy. However, it remains an important drug in tuberculosis therapy and is used primarily in people with severe, possibly life-threatening forms of tuberculosis.

Outbreaks of multidrug-resistant tuberculosis have posed a problem for the prophylactic treatment of exposed people, including health care workers.24 Various treatment protocols are recommended, depending on the type of resistant strain that is identified. Success of chemotherapy for prophylaxis and treatment of tuberculosis depends on strict adherence to a lengthy drug regimen. This often is a problem, particularly for people with asymptomatic tuberculosis infections.

First administered to humans in 1921, the bacillus Calmette-Guérin (BCG) vaccine is used to prevent the development of tuberculosis in people who are at high risk for infection. BCG is an attenuated strain of *M. tuberculosis bovis.* It is administered only to people who have a negative tuberculin skin test result. The vaccine, which is given intradermally, produces a local reaction that can last as long as 3 months and may result in scarring at the injection site. People who have been vaccinated with BCG usually have a positive tuberculin skin test result.

Today, more than 70 years after its development, BCG remains the only tuberculosis vaccine available. Currently, several candidate vaccines are being prepared or are already in the early stages of human testing. Worldwide, BCG is currently used as a major method of prevention for tuberculosis. However, it is not generally recommended in the United States because of the low prevalence of tuberculosis infection, the vaccine’s interference with the ability to determine latent tuberculosis with skin tests, and variable effectiveness against pulmonary tuberculosis.3 Vaccination of health care workers may be considered on an individual basis in settings where people in the hospital are infected with drug-resistant strains of tuberculosis.

### Fungal Infections

Fungi are classified as yeasts and molds. Yeasts are round and grow by budding. Molds form tubular structures called *hyphae* and grow by branching and forming spores. Some fungi are *dimorphic,* meaning that they grow as yeasts at body temperatures and as molds at room temperatures. A simple classification of mycoses or diseases caused by fungi divides them into superficial, cutaneous, subcutaneous, or deep (systemic) mycoses. The superficial, cutaneous, or subcutaneous mycoses cause disease of the skin, hair, and nails. Deep fungal infections may produce pulmonary and systemic infections and are sometimes fatal. Virulent fungi that live free in nature, in soil, or in decaying organic matter cause these infections. They are frequently limited to certain geographic regions.

The most common of these are the dimorphic fungi, which include *H. capsulatum* (histoplasmosis), *C. immitis* (coccidioidomycosis), and *B. dermatitidis* (blastomycosis). These fungi form infectious spores, which enter the body through the respiratory system. Most people who become infected with these fungi develop only minor symptoms or none at all. Only a small minority develops serious disease.

The host’s cell-mediated immune response is paramount in controlling such infections. Pathologic fungi generally produce no toxins. In the host, they induce a delayed cell-mediated hypersensitivity response to their chemical constituents. Cellular immunity is mediated by antigen-specific T lymphocytes and cytokine-activated macrophages that assume fungicidal properties. The primary pulmonary lesions consist of aggregates of macrophages stuffed with organisms, with similar lesions developing in the lymph nodes that drain the area. These lesions develop into granulomas complete with giant cells and may develop central necrosis and calcification resembling that of primary tuberculosis.

Although most fungal infections are asymptomatic, they can be severe or even fatal in people who have experienced a heavy exposure, have underlying immune deficiencies, or develop progressive disease that is not recognized or treated. Immunocompromised people, particularly those with HIV infection, are especially prone to development of disseminated infection.
**Histoplasmosis**

Histoplasmosis is caused by the dimorphic fungus *H. capsulatum*. It is the most common of the mycoses that affect humans. It is the most common of the mycoses that affect humans. Most cases in the United States occur along the major river valleys of the Midwest—the Ohio and the Mississippi. The organism grows in soil and other areas that have been enriched with bird excreta and bat droppings.

**Etiology and Pathogenesis.** The infection is acquired by inhaling the fungal spores that are released when the dirt or dust from the infected areas is disturbed. The spores convert to the parasitic yeast phase when exposed to body temperature in the alveoli. They are then carried to the regional lymphatics and from there are disseminated throughout the body in the bloodstream. Dissemination occurs during the first several weeks of infection before specific immunity has developed. After 2 to 3 weeks, cellular immunity develops as long as the host is immunocompetent, establishing the body’s ability to control the infection.

**Clinical Manifestations.** Depending on the host’s resistance and immunocompetence, the disease usually causes no symptoms and resolves spontaneously. The average incubation period for the infection to cause symptoms is approximately 13 to 17 days after exposure. Most people with *H. capsulatum* infection remain asymptomatic or have mild respiratory illness that is not diagnosed as histoplasmosis. Latent asymptomatic histoplasmosis is characterized by evidence of healed lesions in the lungs or hilar lymph nodes. Primary pulmonary histoplasmosis occurs in otherwise healthy people as a mild, self-limited, febrile respiratory infection. Its symptoms include muscle and joint pains and a nonproductive, dry cough. Erythema nodosum (i.e., subcutaneous nodules) or erythema multiforme (i.e., hive-like lesions) sometimes appears. During this stage of the disease, chest radiographs usually show single or multiple infiltrates.

Chronic histoplasmosis can resemble reactivation tuberculosis. Infiltration of the upper lobes of one or both lungs occurs with cavitation. This form of the disease is more common in middle-aged men who smoke and in people with chronic lung disease. The most common manifestations are a productive cough, chest pain, fever, night sweats, and weight loss. In many people, the disease is self-limited. In others, there is progressive destruction of lung tissue and dissemination of the disease.

Disseminated histoplasmosis can follow primary or chronic histoplasmosis. However, it most often develops as an acute and fulminating infection in the very old or the very young or in people who are immunocompromised, including people who have undergone transplantations, those with hematologic malignacies, and people with AIDS. Although the macrophages of the reticuloendothelial system can remove the fungi from the bloodstream, they are unable to destroy them. Characteristically, this form of the disease produces high fever, generalized lymph node enlargement, hepatosplenomegaly, muscle wasting, anemia, leukopenia, and thrombocytopenia. There may be hoarseness, ulcerations of the mouth and tongue, nausea, vomiting, diarrhea, and abdominal pain. Often, meningitis becomes a dominant feature of the disease.

**Diagnosis and Treatment.** A number of laboratory tests, including cultures, fungal stain, antigen detection, and serologic tests for antibodies, are used in the diagnosis of histoplasmosis. The type of test that is used depends on the type of involvement that is present. In pulmonary disease, sputum culture is rarely positive, whereas blood or bone marrow cultures from immunocompromised people with acute disseminated disease are positive in 80% to 90% of cases. Some people may need a surgical biopsy on their suspicious lung nodule to rule out malignancy. Antigen tests can be performed on blood, urine, cerebrospinal fluid, or bronchoalveolar lavage fluid. A Histoplasma urine antigen assay is particularly useful in detecting disseminated histoplasmosis.

An antifungal drug, such as itraconazole (Sporanox), usually is the drug of choice for treatment of people with disease severe enough to require treatment or those with compromised immune function who are at risk for the development of disseminated disease. For those with immunocompetency, no drug is generally needed since the histoplasmosis tends to resolve spontaneously. People with HIV-related histoplasmosis usually require lifelong suppression therapy with itraconazole.

**Coccidioidomycosis**

Coccidioidomycosis, “valley fever,” is a common fungal infection caused by inhaling the spores of *C. immitis* or *C. posadasii*. The disease resembles tuberculosis, and its mechanisms of infection are similar to those of histoplasmosis. It is most prevalent in the deserts of the southwestern United States, principally in parts of California, Arizona, Nevada, New Mexico, and Texas. The *C. immitis* and *C. posadasii* organism lives in soil and can establish new sites in the soil. Events such as dust storms and digging for construction have been associated with increased incidence of the disease.

**Etiology and Pathogenesis.** The disease resembles tuberculosis, and its mechanisms of infection are similar to those of histoplasmosis. It is most prevalent in the deserts of the southwestern United States, principally in parts of California, Arizona, Nevada, New Mexico, and Texas. The *C. immitis* and *C. posadasii* organism lives in soil and can establish new sites in the soil. Events such as dust storms and digging for construction have been associated with increased incidence of the disease.

**Clinical Manifestations.** The disease most commonly occurs as an acute, primary, self-limited pulmonary infection with or without systemic involvement. However, in some cases it progresses to a disseminated disease. The incubation period is 7 to 21 days. About 40% of infected people develop symptoms of primary coccidioidomycosis. The symptoms are usually those of a respiratory tract infection with fever, cough, and pleuritic pain. Erythema nodosum may occur 2 to 20 days after onset of symptoms. The skin lesions usually are accompanied by arthralgias or arthritis without effusion. The terms *desert bumps* and *desert arthritis* are used to describe these manifestations. The presence of skin and joint manifestations indicates strong host defenses because people who have had such manifestations seldom acquire disseminated disease.

Commonly affected structures in disseminated disease are the lymph nodes, meninges, spleen, liver, kidney, skin, and adrenal glands. Meningitis is the most common cause of death. Persons with diabetes, lung disease, or compromised immune function, infants, smokers, pregnant women, and members of dark-skinned races tend to localize the disease poorly and are at higher risk for disseminated disease.
In HIV-infected people in endemic areas, coccidioidomycosis is now a common opportunistic infection.

Diagnosis and Treatment. Radiologic studies, including chest radiographic studies and bone scans, are useful in determining disease but cannot distinguish coccidioidomycosis from other pulmonary diseases. A definitive diagnosis requires microscopic or serologic evidence that *C. immitis* or *C. posadasii* is present in body tissues or fluids. Spherules can be visualized in specially stained biopsy specimens. Serologic tests can be done for immunoglobulin M (IgM) and IgG antibody detection.32 Treatment depends on the severity of infection. Persons without associated risk factors such as HIV infection or without specific evidence of progressive disease usually can be managed without antifungal therapy, which constitutes approximately 60% of people. The oral antifungal drugs itraconazole and fluconazole are used for treatment of less severe forms of infection.30

**Blastomycosis**

Blastomycosis is a fungal infection caused by inhaling the spores of *B. dermatitidis*. The disease is most commonly found in the southern and central United States, especially in areas bordering the Mississippi and Ohio River basins and the Great Lakes.35 *B. dermatitidis* is most commonly found in soil containing decayed vegetation or decomposed wood. Local suppurative (pus-forming) and granulomatous lesions of the lungs and skin characterize blastomycosis. The symptoms of acute infection, which are similar to those of acute histoplasmosis, include fever, cough, aching joints and muscles, and, uncommonly, pleuritic pain. In contrast to histoplasmosis, the cough in blastomycosis often is productive, and the sputum is purulent. Acute pulmonary infections may be self-limited or progressive. In people with overwhelming pulmonary disease, diffuse interalveolar infiltrates and evidence of acute RDS may develop. Extrapulmonary spread most commonly involves the skin, bones, or prostate. These lesions may provide the first evidence of the disease.

The definitive diagnostic test for *B. dermatitidis* infection is growth of the organism from sputum, tissue biopsy, or body fluid. It generally takes several weeks to grow in mold phase at room temperature. Once growth has occurred, laboratories that use the highly specific and sensitive DNA probe for *B. dermatitidis* can rapidly identify the organism. New diagnostics are being used in clinical trials.36 Treatment of the progressive or disseminated form of the disease includes the use of itraconazole.35 Most people with blastomycosis are identified and treated before the development of overwhelming or fatal disease.

**IN SUMMARY**

Respiratory infections are the most common cause of respiratory illness. They include the common cold, influenza, pneumonias, tuberculosis, and fungal infections. The common cold occurs more frequently than any other respiratory infection. The fingers are the usual source of transmission, and the most common portals of entry are the nasal mucosa and the conjunctiva of the eye. The influenza virus causes three syndromes: an uncomplicated rhinotracheitis, a respiratory viral infection followed by a bacterial infection, and viral pneumonia. The contagiousness of influenza results from the ability of the virus to mutate and form subtypes against which the population is unprotected.

Pneumonia describes an infection of the parenchymal tissues of the lung. Loss of the cough reflex, damage to the ciliated endothelium that lines the respiratory tract, or impaired immune defenses predispose to pneumonia. Pneumonia can be classified according to the setting in which it occurs (community- or hospital-acquired), type of organism causing the infection (typical or atypical), and location of the infection (lobar pneumonia or bronchopneumonia). People with compromised immune function constitute a special concern in both categories. Community-acquired pneumonia involves infections from organisms that are present more often in the community than in the hospital or nursing home. The most common cause of community-acquired pneumonia is *S. pneumoniae*. Hospital-acquired (nosocomial) pneumonia is defined as a lower respiratory tract infection occurring 48 hours or more after admission. Hospital-acquired pneumonia is the second most common cause of hospital-acquired infection. Acute typical pneumonias, including *S. pneumoniae* and *L. pneumophila* pneumonia, are caused by organisms that multiply extracellularly in the alveoli and cause inflammation and transudation of fluid into the air-filled spaces of the alveoli. Atypical pneumonias are caused by a variety of agents, including *M. pneumoniae* and viruses that invade the alveolar septum and interstitium of the lung.

Tuberculosis is a chronic respiratory infection caused by *M. tuberculosis*, which is spread by minute, invisible particles called *droplet nuclei*. Tuberculosis is a particular threat among HIV-infected people, foreign-born people from countries with a high incidence of tuberculosis, and residents of high-risk congregate settings such as correctional facilities, drug treatment facilities, and homeless shelters. The tubercle bacillus incites a distinctive chronic inflammatory response referred to as granulomatous inflammation. The destructiveness of the disease results from the cell-mediated hypersensitivity response that the bacillus evokes rather than its inherent destructive capabilities. Cell-mediated immunity and hypersensitivity reactions contribute to the evolution of the disease. The treatment of tuberculosis has been complicated by outbreaks of drug-resistant forms of the disease.

Infections caused by the fungi *H. capsulatum* (histoplasmosis), *C. immitis* (coccidioidomycosis), and *B. dermatitidis* (blastomycosis) produce pulmonary manifestations that resemble tuberculosis. These infections are common but seldom serious unless they produce progressive destruction of lung tissue or the infection disseminates to organs and tissues outside the lungs.
CANCER OF THE LUNG

After completing this section of the chapter, you should be able to meet the following objectives:

- Compare small cell lung cancer (SCLC) and non–small cell lung cancer (NSCLC) in terms of histopathology, prognosis, and treatment methods.
- Define the term paraneoplastic and cite three paraneoplastic manifestations of lung cancer.

Due to a general decrease in smoking over the past 30 years, the number of Americans who develop lung cancer is decreasing. Yet, lung cancer remains the leading cause of cancer death among men and women in the United States with the average age of diagnosis being 71 years. Smoking among teens has increased in recent years, raising the potential for increased rates of lung cancer in the future. In addition, there has been an increase in smoking and lung cancer rates among American Indians and Alaskan Natives. Currently, the 5-year survival rate for men diagnosed with lung cancer is between 6% and 14%. For women diagnosed with cancer, the 5-year survival rate is between 7% and 18%.

Cigarette smoking causes more than 80% of cases of lung cancer. The risk for lung cancer among cigarette smokers increases with duration of smoking and the number of cigarettes smoked per day. Cigarette smokers can benefit at any age from increases with duration of smoking and the number of cigarettes smoked per day. Cigarette smokers can benefit at any age from smoking cessation. Tobacco smoke contributes heavily to the development of lung cancer in people exposed to asbestos. The mean risk for lung cancer is significantly greater in asbestos workers compared to the general population. In addition, tobacco smoke contributes heavily to the development of lung cancer in people exposed to asbestos. In addition to cigarette smoking and industrial hazards, there is also evidence to suggest a familial predisposition to lung cancer. This occurrence may be due to a genetic predisposition, with the trait being expressed only in the presence of its major predisposing factor—cigarette smoking. Finally, there is an increased incidence in lung cancer in people who have never smoked, including those exposed to smoking and even in those not exposed to smoking.

Histologic Subtypes and Pathogenesis

Most (about 95%) primary lung tumors are carcinomas that arise from the lung tissue. The remaining 5% are a miscellaneous group that includes bronchial carcinoid tumors (neuroendocrine tumors), bronchial gland tumors, fibrosarcomas, and lymphomas. The lung is also a frequent site of metastasis from cancers in other parts of the body.

Lung cancers are being identified recently as aggressive or nonaggressive, locally invasive, and widely metastatic tumors that arise from the epithelial lining of major bronchi. These tumors begin as small mucosal lesions that may follow one of several patterns of growth. They may form intraluminal masses that invade the bronchial mucosa and infiltrate the peribronchial connective tissue, or they may form large, bulky masses that extend into the adjacent lung tissue. Some large tumors undergo central necrosis and acquire local areas of hemorrhage, and some invade the pleural cavity and chest wall and spread to adjacent intrathoracic structures. All types of lung cancer, especially small cell lung carcinoma, have the capacity to synthesize bioactive products and produce paraneoplastic syndromes. These syndromes are a result of hormonal production of ectopic peptide by the tumor or from autoantibodies released in response to the tumor. Generally the paraneoplastic syndromes are of endocrine, neurologic, and/or immunologic etiology.

Lung cancer is commonly subdivided into four major categories with percentages of occurrence in each category. These include squamous cell lung carcinoma (25% to 40%), adenocarcinoma (20% to 40%), small cell carcinoma (20% to 25%), and large cell carcinoma (10% to 15%). However, new diagnostic techniques allow more lung cancers to be detected at an earlier stage. This has led to changes being made in the percentages of occurrence in the major categories of lung cancer. For example, in 2011, the adenocarcinomas are estimated to account for 35% to 50% of all lung cancers. For purposes of staging and treatment, lung cancers have been commonly identified as SCLC or NSCLC. The key reason for this classification was that most SCLCs have metastasized by the time of diagnosis and were therefore not amenable to surgery. However, new protocols are being used today in many of the large oncology centers that involve lung cancer biomarkers and new molecular targeted therapies for different types of lung cancer. In fact, a whole new classification system of lung cancers is evolving where non–small cell carcinoma is being used less frequently and large cell carcinoma is being replaced by large cell neuroendocrine carcinoma.

Small Cell Lung Cancers

The SCLCs are characterized by a distinctive cell type—small round to oval cells that are approximately the size of a lymphocyte. The cells grow in clusters that exhibit neither glandular nor squamous organization. Electron microscopic studies demonstrate the presence of neurosecretory granules in some of the tumor cells similar to those found in the bronchial epithelium of the fetus or neonate. The presence of these granules suggests the ability of some of these tumors to secrete polypeptide hormones. The presence of neuroendocrine markers such as neuron-specific enolase and parathormone-like and other hormonally active products suggests that these tumors may arise from the neuroendocrine cells of the bronchial epithelium. This cell type has the strongest association with cigarette smoking and is rarely observed in someone who has not smoked.

The SCLCs are highly malignant, tend to infiltrate widely, disseminate early in their course, and rarely are resectable. Brain metastases are particularly common with SCLC and may provide the first evidence of the tumor. This type of lung cancer is associated with several types of paraneoplastic syndrome, including the syndrome of inappropriate antidiuretic hormone secretion, Cushing syndrome associated
with ectopic production of adrenocorticotropic hormone, and the Eaton-Lambert syndrome of neuromuscular disorder.

**Non–Small Cell Lung Cancers**
The NSCLCs include squamous cell carcinomas, adenocarcinomas, and large cell carcinomas (see Fig. 36.11). Like the SCLCs, these cancers have the capacity to synthesize bioactive products and produce paraneoplastic syndromes.

**Squamous Cell Carcinoma.** Squamous cell carcinoma is found most commonly in men and is closely correlated with a smoking history. Squamous cell carcinoma tends to originate in the central bronchi as an intraluminal growth and is thus more amenable to early detection through cytologic examination of the sputum than other forms of lung cancer. It tends to spread centrally into major bronchi and hilar lymph nodes and disseminates outside the thorax later than other types of bronchogenic cancers. Squamous cell carcinoma is associated with the paraneoplastic syndromes that produce hypercalcemia.

**Adenocarcinoma.** Currently, adenocarcinoma is the most common type of lung cancer in North America. Its association with cigarette smoking is weaker than for squamous cell carcinoma. It is the most common type of lung cancer in women and nonsmokers. Adenocarcinomas can have their origin in either the bronchiolar or alveolar tissues of the lung. These tumors tend to be located more peripherally than...
Chapter 36  Respiratory Tract Infections, Neoplasms, and Childhood Disorders

squamous cell sarcomas and sometimes are associated with areas of scarring (Fig. 36.12). The scars may be due to old infarcts, metallic foreign bodies, wounds, and granulomatous infections such as tuberculosis. In general, adenocarcinomas have a poorer stage-for-stage prognosis than squamous cell carcinomas.

**Large Cell Carcinoma.** Large cell carcinomas have large, polygonal cells. They constitute a group of neoplasms that are highly anaplastic and difficult to categorize as squamous cell carcinoma or adenocarcinoma. They tend to occur in the periphery of the lung, invading subsegmental bronchi and larger airways. They have a poor prognosis because of their tendency to spread to distant sites early in their course.

**Clinical Manifestations**

The manifestations of lung cancer can be divided into three categories:

1. Those due to involvement of the lung and adjacent structures
2. The effects of local spread and metastasis
3. Nonmetastatic paraneoplastic manifestations involving endocrine, neurologic, and connective tissue function

As with other cancers, lung cancer also causes nonspecific symptoms such as anorexia and weight loss. Because its symptoms are similar to those associated with smoking and chronic bronchitis, they often are disregarded. Metastases already exist in many people presenting with evidence of lung cancer (see Fig. 36.13). The most common sites of these metastases are the brain, bone, and liver.

Many of the manifestations of lung cancers result from local irritation and obstruction of the airways and from invasion of the mediastinum and pleural space. The earliest symptoms usually are chronic cough, shortness of breath, and wheezing because of airway irritation and obstruction. Hemoptysis (i.e., blood in the sputum) occurs when the lesion erodes blood vessels. Pain receptors in the chest are limited to the parietal pleura, mediastinum, larger blood vessels, and peribronchial afferent vagal fibers. Dull, intermittent, poorly localized retrosternal pain is common in tumors that involve the mediastinum. Pain becomes persistent, localized, and more severe when the disease invades the pleura.

Tumors that invade the mediastinum may cause hoarseness because of the involvement of the recurrent laryngeal nerve and cause difficulty in swallowing because of compression of the esophagus. An uncommon complication called the *superior vena cava syndrome* occurs in some people with mediastinal involvement. Interruption of blood flow in this vessel usually results from compression by the tumor or involved lymph nodes. The disorder can interfere with venous drainage from the head, neck, and chest wall. The outcome is determined by the speed with which the disorder develops and the adequacy of the collateral circulation. Tumors adjacent to the visceral pleura often insidiously produce pleural effusion. This effusion can compress the lung and cause atelectasis and dyspnea. It is less likely to cause fever, pleural friction rub, or pain than pleural effusion resulting from other causes.

**Diagnosis and Treatment**

The diagnosis of lung cancer is based on a careful history and physical examination and on other tests such as chest radiography, bronchoscopy, cytologic studies of the sputum or bronchial washings, percutaneous needle biopsy of lung tissue, and scalene lymph node biopsy. CT scans, MRI studies, and ultrasonography are used to locate lesions and evaluate the extent of the disease. Positron emission tomography (PET) is a noninvasive alternative for identifying metastatic lesions in the mediastinum or distant sites. Persons with SCLC should also have a CT scan or MRI of the brain for detection of metastasis.

Like other cancers, lung cancer is classified according to extent of disease, NSCLCs are usually classified according to cell type (i.e., squamous cell carcinoma, adenocarcinoma, and large cell carcinoma) and staged according to the TNM international staging system. SCLCs are not staged using the TNM system because micrometastases are assumed to be present at the time of diagnosis. Instead, they are usually classified as limited disease when the tumor is limited to the unilateral hemithorax, or extensive disease when it extends beyond these boundaries.

Treatment methods for NSCLC include surgery, radiation therapy, and chemotherapy. These treatments may be used singly or in combination. Surgery is used for the removal of small, localized NSCLC tumors. It can involve a lobectomy, pneumonectomy, or segmental resection of the lung. Radiation therapy can be used as a definitive or main treatment modality, as part of a combined treatment plan.
or for palliation of symptoms. Because of the frequency of metastases, chemotherapy often is used in treating lung cancer. Combination chemotherapy, which uses a regimen of several drugs, usually is used. New targeted treatments are under development with the goal of increasing survival and ultimately providing a cure for this type of cancer.

Therapy for SCLC is based on chemotherapy and radiation therapy, but this is changing as new therapies are developed. Advances in the use of combination chemotherapy, along with thoracic irradiation, have improved the outlook for people with SCLC. Because SCLC may metastasize to the brain, prophylactic cranial irradiation is often indicated. In most people who achieve a complete remission from SCLC, the brain is the most frequent site of relapse. About half of these people develop clinical metastasis within 3 years. Newer combination chemotherapy regimens and targeted therapies are being developed in hopes of providing treatment alternatives that increase survival and produce fewer treatment liabilities.

Management of Lung Cancer in Older Adults

Given the fact that most people are older than 65 years of age when diagnosed with lung cancer, it is important to understand management of lung cancer in older adults. Knowledge about the optimal treatment for older adults is limited because of underrepresentation in clinical trials and failure to evaluate younger versus older people in randomized clinical trials. At present, it is recommended that older adults should be treated based on their general physiologic rather than chronologic age. This includes an evaluation of functional status (ability to be independent in daily tasks at home and in the community), coexisting medical conditions, nutritional status, cognition, psychological functioning, social support, and medication review. Those with good performance status and normal renal and hematologic parameters may be treated surgically or receive standard chemotherapy and radiation for limited-stage disease and combination chemotherapy for extensive-stage disease.

Surgery remains the mainstay for older adults with stages I to III NSCLC. Curative resection is feasible in older adults. The challenge for surgical treatment for older adults is age-related physiologic changes in cardiovascular and respiratory systems that may affect tolerance of surgery.

Radiation can be given with curative intent for older adults who are not surgical candidates. It may also be used for palliation of cancer-related symptoms. Evidence suggests that treatment tolerance and efficacy of thoracic radiation are similar in younger and older people. Age is reported to have no effect on acute or late radiation toxicity, including nausea, dyspnea, esophagitis, or weakness. Chemotherapy is the mainstay of treatment of SCLC. Older adults with good performance status may receive standard chemotherapy for limited disease and combination chemotherapy for extensive-stage disease. Some older adults may require dose reductions or be unable to complete the full chemotherapy course.

IN SUMMARY

Cancer of the lung is a leading cause of death worldwide. Cigarette smoking is implicated in the majority of cases of lung cancer. The risk for lung cancer among cigarette smokers increases with duration of smoking and the number of cigarettes smoked per day. Industrial hazards, such as exposure to asbestos, increase the risk for development of lung cancer. Because lung cancer develops insidiously, it often is far advanced before it is diagnosed. This fact explains the poor 5-year survival rate. Carcinoma, which accounts for 95% of all primary lung cancers, can be subdivided currently into four major categories: squamous cell carcinoma, adenocarcinoma, large cell carcinoma, and small cell carcinoma. For purposes of staging and treatment, lung cancer is divided into SCLC and NSCLC. The main reason for this is that almost all SCLCs have metastasized at the time of diagnosis.

The manifestations of lung cancer can be attributed to the involvement of the lung and adjacent structures, the effects of local spread and metastasis, and paraneoplastic syndromes involving endocrine, neurologic, and hematologic dysfunction. As with other cancers, lung cancer causes nonspecific symptoms such as anorexia and weight loss. Treatment methods for lung cancer include surgery, irradiation, and chemotherapy. The current increase in lung cancer among older adults (those 65 years of age and older) has required a rethinking of the treatment strategies for this age group, with the trend being to base treatment on physiologic rather than chronologic age.

RESPIRATORY DISORDERS IN CHILDREN

After completing this section of the chapter, you should be able to meet the following objectives:

- Describe the role of surfactant in lung function in the neonate.
- Describe the possible cause and manifestations of RDS and bronchopulmonary dysplasia.
- List the signs of impending respiratory failure in small children.

Acute respiratory diseases are the most common cause of illness in infancy and childhood. This section focuses on

- Lung development, with an emphasis on the developmental basis for lung disorders in children
- Respiratory disorders in the neonate
- Respiratory infections in children

Lung Development

Although other body systems are physiologically ready for extrauterine life as early as 25 weeks of gestation, the lungs require much longer. Immaturity of the respiratory system
is a major cause of morbidity and mortality in infants born prematurely. Even at birth, the lungs are not fully mature, and additional growth and maturation continue well into childhood.

Lung development may be divided into five stages: embryonic period, pseudoglandular period, canalicular period, saccular period, and alveolar period. The development of the respiratory system begins with the embryonic period (weeks 4 to 6 of gestation). During this period, a rudimentary bronchial bud branches from the esophagus to begin formation of the airways and alveolar spaces. The bronchial bud divides into two lung buds that grow laterally. The right bud gives rise to two secondary bronchial buds and the left bud to one secondary bronchial bud. Consequently, at maturity, there are three main (primary) bronchi and three lung lobes on the right and only two main bronchi and two lung lobes on the left. Each secondary bronchial bud subsequently undergoes continuous branching. The tertiary (segmental) bronchi (10 in the right lung and 8 or 9 in the left lung) begin to form during the seventh week. The pulmonary vasculature is a mesenchymal derivative. Soon after their appearance, the bronchial buds are surrounded by a vascular plexus, which originates from the aorta and drains into the major somatic veins. This vascular plexus connects with the pulmonary artery and veins at the seventh week of gestation.

During the pseudoglandular period (weeks 5 to 16), the lungs resemble a gland. During this period, the conducting airways are formed. At 17 weeks, all of the major elements of the lung have formed except the gas exchange structures. Respiration is not possible because the airways end in blind tubes. The canalicular period (weeks 17 to 27) marks the formation of the primitive alveoli. The lumina of the bronchi and bronchioles become much larger, and the lung tissue becomes more highly vascularized. By the 24th week, each bronchiole has given rise to two or more respiratory bronchioles. Respiration is possible at this time because some primitive alveoli have developed at the ends of the bronchioles. The saccular period (weeks 27 to 35) is devoted to the development of the terminal alveolar sacs, which facilitate gas exchange. During this period, the terminal sacs thin out, and capillaries begin to bulge into the terminal sacs. These thin cells are known as type I alveolar cells. By the 25th to 28th weeks, sufficient terminal sacs are present to permit survival. Before this time, the premature lungs are incapable of adequate gas exchange. It is not so much the presence of the thin alveolar epithelium as it is the adequate matching of pulmonary vasculature to it that is critical to survival. Type II alveolar cells begin to develop at approximately 24 weeks. These cells produce surfactant, a substance capable of lowering the surface tension of the air–alveoli interface. By the 28th to 30th weeks, sufficient amounts of surfactant are available to prevent alveolar collapse when breathing begins.

The alveolar period (late fetal to early childhood) marks the maturation and expansion of the alveoli. Starting as early as 30 weeks and usually by 36 weeks of gestation, the saccular structures become alveoli. Alveolar development is characterized by thinning of the pulmonary interstitium and the appearance of a single-capillary network, in which one capillary bulges into each terminal alveolar sac. By the late fetal period, the lungs are capable of respiration because the alveolar–capillary membrane is sufficiently thin to allow for gas exchange.

Although transformation of the lungs from gland-like structures to highly vascular, alveoli-like organs occurs during the late fetal period, mature alveoli do not form for some time after birth. The growth of the lung during infancy and early childhood involves an increase in the number rather than the size of the alveoli. Only one eighth to one sixth of the adult number of alveoli is present at birth. There is a relative slowing of alveolar growth during the first 3 months after birth, and this is followed by a rapid increase in alveolar number during the rest of the first year of life.

**Development of Breathing in the Fetus and Neonate**

The fetal lung is a secretory organ, and fluids and electrolytes are secreted into the potential air spaces. This fluid appears to be important in stimulating alveolar development. For the fetus to complete the transition from intrauterine to extraterine life, this fluid must be cleared from the lung soon after birth. Presumably with the onset of labor, the secretion of fluid ceases. During the birth process, pressure on the fetal thorax causes the fluid to be expelled from the mouth and nose. When the lungs expand after birth, the fluid moves into the tissues surrounding the alveoli and is then absorbed into the pulmonary capillaries or removed by the lymphatic system.

Fetal breathing movements occur in utero. These movements are irregular in rate and amplitude, ranging from 30 to 70 breaths/minute, and become more rapid as gestation advances. Because they are rapid and shallow, these movements do not result in movement of fluid into or out of the fetal lung. Instead, they are thought to condition the respiratory muscles and stimulate lung development. The breathing movements in the fetus become more rapid in response to an increase in carbon dioxide levels and become slower in response to hypoxia.

The major difference between respiration in the fetus and the neonate is that there is complete separation between gas exchange and breathing movements in the fetus. The gas supply and exchange depend entirely on maternal mechanisms controlling placental circulation. At birth, dependence on the placental circulation is terminated, and the infant must integrate the two previously separate functions of gas exchange and respiratory movements. Within seconds of clamping the umbilical cord, the infant takes its first breath, and rhythmic breathing begins and persists for life.

Effective ventilation requires coordinated interaction between the muscles of the upper airways, including those of the pharynx and larynx, the diaphragm, and the intercostal muscles of the chest wall. In infants, a specific sequence of upper airway nerve and muscle activity occurs before and early in inspiration. The tongue moves forward to prevent airway obstruction, and the vocal cord abducts, reducing
laryngeal resistance. By moving downward, the action of the diaphragm increases chest volume in both the longitudinal and transverse directions. In the infant, the diaphragm inserts more horizontally than in the adult. As a result, contraction of the diaphragm tends to draw the lower ribs inward, especially if the infant is placed in the horizontal position. The function of the intercostal muscles is to lift the ribs during inspiration. In the infant, however, the intercostal muscles are not fully developed, so they function largely to stabilize the chest rather than lift the chest wall.

The chest wall of the neonate is highly compliant. Although this is advantageous during the birth process in that it allows for marked distortion to occur without damaging chest structures, it has implications for ventilation during the postnatal period. A striking characteristic of neonatal breathing is the paradoxical inward movement of the upper chest during inspiration, especially during active sleep. This occurs because of decreased activity of the intercostal muscles during active sleep, which allows the contracting diaphragm to pull the highly compliant chest wall inward. Under circumstances such as crying, the intercostal muscles of the neonate function together with the diaphragm to splint the chest wall and prevent its collapse.

Normally, the infant’s lungs also are compliant. This is advantageous to the infant with a compliant chest cage because it takes only small changes in inspiratory pressure to inflate a compliant lung. When respiratory disease develops, lung compliance is reduced, and it takes more effort to inflate the lungs. The diaphragm must generate more negative pressure, causing the compliant chest wall structures to be sucked inward. Retractions are abnormal inward movements of the chest wall during inspiration. They may occur intercostally (between the ribs), in the substernal or epigastric area, and in the supraclavicular spaces. Because the chest wall of the infant is compliant, substernal retractions become more obvious with small changes in lung function. Retractions can indicate airway obstruction or atelectasis.

Airway Resistance
Normal lung inflation requires uninterrupted movement of air through the extrathoracic airways (i.e., nose, pharynx, larynx, and upper trachea) and intrathoracic airways (i.e., bronchi and bronchioles). The neonate (0 to 4 weeks of age) breathes predominantly through the nose and does not adapt well to mouth breathing. Any obstruction of the nose or nasopharynx may increase upper airway resistance and increase the work of breathing.

The airways of the infant and small child are much smaller than those of the adult.40 Because the resistance to airflow is inversely related to the fourth power of the radius (resistance = 1/r^4), relatively small amounts of mucus secretion, edema, or airway constriction can produce marked changes in airway resistance and airflow. Nasal flaring is a method that infants use to take in more air. This method of breathing increases the size of the nares and decreases the resistance of the small airways.

Normally, the extrathoracic airways in the infant narrow during inspiration and widen during expiration, and the intrathoracic airways widen during inspiration and narrow during expiration.40 This occurs because the pressure inside the extrathoracic airways reflects the intrapleural pressures that are generated during breathing, whereas the pressure outside the airways is similar to atmospheric pressure. Thus, during inspiration, the pressure inside becomes more negative, causing the airways to narrow, and during expiration it becomes more positive, causing them to widen. In contrast to the extrathoracic airways, the pressure outside the intrathoracic airways is equal to the intrapleural pressure. These airways widen during inspiration as the surrounding intrapleural pressure becomes more negative and pulls them open, and they narrow during expiration as the surrounding pressure becomes more positive.

Lung Volumes and Gas Exchange
The functional residual capacity, which is the air left in the lungs at the end of normal expiration, plays an important role in the infant’s gas exchange. In the infant, the functional residual capacity occurs at a higher lung volume than in the older child or adult.43 This higher end-expiratory volume results from a more rapid respiratory rate, which leaves less time for expiration. However, the increased residual volume is important to the neonate for several reasons: (1) it holds the airways open throughout all phases of respiration, (2) it favors the reabsorption of intrapulmonary fluids, and (3) it maintains more uniform lung expansion and enhances gas exchange. During active sleep, the tone of the upper airway muscles is reduced. Therefore, the time spent in expiration is shorter, and the intercostal activity that stabilizes the chest wall is less. This results in a lower end-expiratory volume and less optimal gas exchange.

Control of Ventilation
Fetal arterial oxygen pressures (PO2) normally range from 25 to 30 mm Hg, and carbon dioxide pressures (PCO2) range from 45 to 50 mm Hg, independent of any respiratory movements. Any decrease in oxygen levels induces quiet sleep in the fetus with subsequent cessation of breathing movements, both of which lead to a decrease in oxygen consumption. Switching to oxygen derived from the aerated lung at birth causes an immediate increase in arterial PO2 to approximately 50 mm Hg; within a few hours, it increases to approximately 70 mm Hg.41 These levels, which greatly exceed fetal levels, cause the chemoreceptors that sense arterial PO2 levels to become silent for several days. Although the infant’s arterial PO2 may fluctuate during this critical time, the chemoreceptors do not respond appropriately. It is not until several days after birth that the chemoreceptors “reset” their PO2 threshold. Only then do they become the major controller of breathing. However, the response seems to be biphasic, with an initial hyperventilation followed by a decreased respiratory rate and even apnea. Periodic breathing and apnea are characteristic of premature infants and reflect patterns of fetal breathing.
Chapter 36  Respiratory Tract Infections, Neoplasms, and Childhood Disorders

Respiratory Disorders in the Neonate

The neonatal period is one of transition from placental dependency to air breathing. This transition requires functioning of the surfactant system, conditioning of the respiratory muscles, and establishment of parallel pulmonary and systemic circulations. Respiratory disorders develop in infants who are born prematurely or who have other problems that impair this transition. Among the respiratory disorders of the neonate are the RDS and bronchopulmonary dysplasia.

Respiratory Distress Syndrome

Respiratory distress syndrome (RDS), also known as hyaline membrane disease, is one of the most common causes of respiratory disease in premature infants. In these infants, pulmonary immaturity, together with surfactant deficiency, leads to alveolar collapse (Fig. 36.15).

Increased airway resistance can occur in either the extrathoracic or intrathoracic airways. When the obstruction is in the extrathoracic airways, inspiration is more prolonged than expiration. Nasal flaring (enlargement of the nares) helps reduce the nasal resistance and maintain airway patency. It can be a sign of increased work of breathing and is a significant finding in an infant. Inspiratory retractions, or pulling in of the soft tissue surrounding the cartilaginous and bony thorax, are often observed with airway obstruction in infants and small children (Fig. 36.14). In conditions such as croup, the pressures distal to the point of obstruction must become more negative to overcome the resistance; this causes collapse of the distal airways, and the increased turbulence of air moving through the obstructed airways produces an audible crowing sound called a stridor during inspiration.

When the obstruction is in the intrathoracic airways, as occurs with bronchiolitis and bronchial asthma, expiration is prolonged and the child makes use of the accessory expiratory muscles (abdominals). Rib cage retractions may also be present. Intrapleural pressure becomes more positive during expiration because of air trapping. This causes collapse of intrathoracic airways and produces an audible wheezing or whistling sound during expiration.

Manifestations of Respiratory Disorders or Infection in the Infant or Small Child

Most respiratory disorders in the infant or small child produce a decrease in lung compliance or an increase in airway resistance manifested by changes in breathing patterns, rib cage distortion (retractions), audible sounds, and use of accessory muscles.40

Children with restrictive lung disorders, such as pulmonary edema or RDS, breathe at faster rates, and their respiratory excursions are shallow. Grunting is an audible noise emitted during expiration. An expiratory grunt is common as the child tries to raise the end-expiratory pressure and thus prolong the period of oxygen and carbon dioxide exchange across the alveolar-capillary membrane.

Increased airway resistance can occur in either the extrathoracic or intrathoracic airways. When the obstruction is in the extrathoracic airways, inspiration is more prolonged than expiration. Nasal flaring (enlargement of the nares) helps reduce the nasal resistance and maintain airway patency. It can be a sign of increased work of breathing and is a significant finding in an infant. Inspiratory retractions, or pulling in of the soft tissue surrounding the cartilaginous and bony thorax, are often observed with airway obstruction in infants and small children (Fig. 36.14). In conditions such as croup, the pressures distal to the point of obstruction must become more negative to overcome the resistance; this causes collapse of the distal airways, and the increased turbulence of air moving through the obstructed airways produces an audible crowing sound called a stridor during inspiration.

When the obstruction is in the intrathoracic airways, as occurs with bronchiolitis and bronchial asthma, expiration is prolonged and the child makes use of the accessory expiratory muscles (abdominals). Rib cage retractions may also be present. Intrapleural pressure becomes more positive during expiration because of air trapping. This causes collapse of intrathoracic airways and produces an audible wheezing or whistling sound during expiration.

FIGURE 36.14  • (A) Normal inspiratory appearance of the chest during unobstructed breathing in the neonate. (B) Sternal and intercostal retractions during obstructed breathing in the neonate.

FIGURE 36.15  • Pathogenesis of RDS in the infant.
delivery by cesarean section (when performed before the 38th week of gestation).

**Etiology and Pathogenesis.** The type II alveolar cells that produce surfactant do not begin to mature until approximately the 25th to 28th weeks of gestation. Consequently, many premature infants are born with poorly functioning type II alveolar cells and have difficulty producing sufficient amounts of surfactant.

Surfactant synthesis is influenced by several hormones, including insulin and cortisol. Insulin tends to inhibit surfactant production; this explains why infants of insulin-dependent diabetic mothers are at increased risk for development of RDS. Cortisol can accelerate maturation of type II cells and formation of surfactant. The reason that premature infants born by cesarean section presumably are at greater risk for development of RDS is that they are not subjected to the stress of vaginal delivery, which is thought to increase the infants’ cortisol levels. Surfactant reduces the surface tension in the alveoli, thereby equalizing the respiratory forces in the large and small alveoli and reducing the amount of pressure needed to inflate and hold the alveoli open. Without surfactant, the large alveoli remain inflated, whereas the small alveoli become difficult to inflate. At birth, the first breath requires high inspiratory pressures to expand the lungs. With normal levels of surfactant, the lungs retain up to 40% of the residual volume after the first breath, and subsequent breaths require far lower inspiratory pressures. With a surfactant deficiency, the lungs collapse between breaths, making the infant work as hard with each successive breath as with the first breath. The airless portions of the lungs become stiff and noncompliant. A hyaline membrane forms inside the alveoli as protein- and fibrin-rich fluids are pulled into the alveolar spaces. The fibrin–hyaline membrane forms inside the alveoli as protein- and fibrin-rich fluids are pulled into the alveolar spaces. The fibrin–hyaline membrane constitutes a barrier to gas exchange, leading to hypoxemia and carbon dioxide retention, a condition that fur-

Clinical Manifestations. Infants with RDS present with multiple signs of respiratory distress, usually within the first 24 hours of birth. Central cyanosis is a prominent sign. Breathing becomes more difficult, and retractions occur as the infant’s soft chest wall is pulled in as the diaphragm descends. Grunting sounds accompany expiration. As the tidal volume drops because of atelectasis, the respiration rate increases (usually to 60 to 120 breaths/minute) in an effort to maintain normal minute ventilation. Fatigue may develop rapidly because of the increased work of breathing. The stiff lungs of infants with RDS also increase the resistance to blood flow in the pulmonary circulation. As a result, a hemodynamically significant patent ductus arteriosus may develop in infants with RDS.

**Treatment.** The basic principles of treatment for infants with suspected RDS focus on the provision of supportive care, including gentle handling and minimal disturbance. An incubator or radiant warmer is used to prevent hypothermia and increased oxygen consumption. Continuous cardiorespiratory monitoring is needed. Monitoring of blood glucose and prevention of hypoglycemia are also recommended. Oxygen levels can be assessed through an arterial (umbilical) line or by a transcutaneous oxygen sensor. Treatment includes administration of supplemental oxygen, continuous positive airway pressure through nasal prongs, and often assisted mechanical ventilation.

Exogenous surfactant therapy is used to prevent and treat RDS. There are two types of surfactants: natural surfactants prepared from animal sources and synthetic surfactants. The surfactants are suspended in saline and administered into the airways, usually through an endotracheal tube. The treatment often is initiated soon after birth in infants who are at high risk for RDS.

**Bronchopulmonary Dysplasia**

Bronchopulmonary dysplasia (BPD) is a chronic lung disease that develops in premature infants who were treated with long-term mechanical ventilation, mainly for RDS. The condition is considered to be present if the neonate is oxygen dependent at 36 weeks after gestation.

**Etiology.** The disorder is thought to be a response of the premature lung to early injury. High-inspired oxygen concentration and injury from positive-pressure ventilation (i.e., barotrauma) have been implicated.

**Clinical Manifestations.** BPD is characterized by chronic respiratory distress, persistent hypoxemia when breathing room air, reduced lung compliance, increased airway resistance, and severe expiratory flow limitation. There is a mismatching of ventilation and perfusion with development of hypoxemia and hypercapnia. Pulmonary vascular resistance may be increased and pulmonary hypertension and cor pulmonale (i.e., right heart failure associated with lung disease) may develop. The infant with BPD often demonstrates a barrel chest, tachycardia, rapid and shallow breathing, chest retractions, cough, and poor weight gain. Clubbing of the fingers occurs in children with severe disease. Hepatomegaly and periorbital edema may develop in infants with right heart failure.

The treatment of BPD includes mechanical ventilation and administration of supplemental oxygen. Weaning from ventilation is accomplished gradually, and some infants may require ventilation at home. Rapid lung growth occurs during the first year of life, and lung function usually improves. Most adolescents and young adults who had severe BPD during infancy have some degree of pulmonary dysfunction, consisting of airway obstruction, airway hyperreactivity, or hyperinflation.

**Respiratory Infections in Children**

In children, respiratory tract infections are common, and although they are troublesome, they usually are not serious. Frequent infections occur because the immune system of
infants and small children has not been exposed to many common pathogens. Consequently, they tend to contract infections with each new exposure. Although most of these infections are not serious, the small size of an infant’s or child’s airways tends to foster impaired airflow and obstruction. For example, an infection that causes only sore throat and hoarseness in an adult may result in serious airway obstruction in a small child.

**Upper Airway Infections**

Significant acute upper airway infections in infants and small children include viral croup, bacterial tracheitis, and epiglottitis. Croup is the more common and usually is benign and self-limited. Bacterial tracheitis is rare but can occur in children experiencing multiple viral respiratory infections. Epiglottitis is a rapidly progressive and life-threatening condition. The characteristics of croup and epiglottitis infections are described in Table 36.2.

Obstruction of the upper airways because of infection tends to exert its greatest effect during the inspiratory phase of respiration. Movement of air through an obstructed upper airway, particularly the vocal cords in the larynx, causes stridor. Impairment of the expiratory phase of respiration also can occur, causing wheezing. With mild to moderate obstruction, inspiratory stridor is more prominent than expiratory wheezing because the airways tend to dilate with expiration. When the swelling and obstruction become severe, the airways no longer can dilate during expiration, and both stridor and wheezing occur.

Cartilaginous support of the trachea and the larynx is poorly developed in infants and small children. These structures are soft and tend to collapse when the airway is obstructed and the child cries, causing the inspiratory pressures to become more negative. When this happens, the stridor and inspiratory effort are increased. The phenomenon of airway collapse in the small child is analogous to what happens when a thick beverage, such as a milkshake, is drunk through a soft paper or plastic straw. The straw collapses when the negative pressure produced by the sucking effort exceeds the flow of liquid through the straw.

**Viral Croup.** Croup is characterized by inspiratory stridor, hoarseness, and a barking cough. The British use the term croup to describe the cry of the crow or raven, and this is undoubtedly how the term originated.

Viral croup, more appropriately called *acute laryngotracheobronchitis*, is a viral infection that affects the larynx, trachea, and bronchi. The parainfluenza viruses account for approximately 75% all cases. The remaining 25% are caused by adenoviruses, RSV, influenza A and B viruses, and measles virus. Viral croup usually is seen in children 3 months to 5 years of age. The condition may affect the entire laryngotracheal tree. However, because the subglottic area is the narrowest part of the respiratory tree in this age group, the obstruction usually is greatest in this area. Although the respiratory manifestations of croup often appear suddenly, they usually are preceded by upper respiratory infections that cause rhinorrhea (*i.e.*, runny nose), coryza (*i.e.*, common cold), hoarseness, and low-grade fever. In most children, the manifestation of croup advances only to stridor and slight dyspnea before they begin to recover. The symptoms usually

subside when the child is exposed to moist air. For example, letting the bathroom shower run and then taking the child into the bathroom often brings prompt and dramatic relief of symptoms. Exposure to cold air also seems to relieve the airway spasm. Often, severe symptoms are relieved simply because the child is exposed to cold air on the way to the hospital emergency department. Viral croup does not respond to antibiotics, and expectorants, bronchodilating agents, and antihistamines are not helpful. The child should be disturbed as little as possible and carefully monitored for signs of respiratory distress.

Airway obstruction may progress in some children. As obstruction increases, the stridor becomes continuous and is associated with nasal flaring with substernal and intercostal retractions. Agitation and crying aggravate the signs and symptoms, and the child prefers to sit up or be held upright. In the cyanotic, pale, or obstructed child, any manipulation of the pharynx, including use of a tongue depressor, can cause cardiorespiratory arrest and should be done only in a medical setting that has the facilities for emergency airway management. Establishment of an artificial airway may become necessary in severe airway obstruction.

**Spasmodic Croup.** Spasmodic croup manifests with symptoms similar to those of acute viral croup. Because the child is afebrile and lacks other manifestations of the viral prodrome, it is thought to have an allergic origin. Spasmodic croup characteristically occurs at night and tends to recur with respiratory tract infections. The episode usually lasts several hours and may recur several nights in a row.

Most children with spasmodic croup can be managed effectively at home. An environment of high humidification (i.e., cold-water room humidifier or taking the child into a bathroom with a warm, running shower) lessens irritation and prevents drying of secretions. Or, if there is no success with opening the airway, the child should be brought outside into the cold air, which, in some cases, can assist the child’s breathing.

**Bacterial Tracheitis.** This disorder is also called laryngotracheobronchitis and bacterial croup. It is a rare infection of the trachea secondary to a bacterium, most often *S. aureus*. If seen, it generally follows a viral respiratory infection. The manifestations are similar to viral croup except the child will need an antibiotic since a bacterium causes the infection. These children will need to be diagnosed and treated quickly; otherwise, acute respiratory failure can occur.

**Epiglottitis.** Acute epiglottitis is a dramatic, potentially fatal condition characterized by inflammatory edema of the supraglottic area, including the epiglottis and pharyngeal structures (see Fig. 36.14). It comes on suddenly, bringing danger of airway obstruction and asphyxia.\(^4^0\) In the past, the *H. influenzae* type B bacterium was the most commonly identified etiologic agent. It is seen less commonly since the widespread use of immunization against *H. influenzae* type B. Therefore, other agents such as *Streptococcus pyogenes*, *S. pneumoniae*, and *S. aureus* now represent the larger cause of pediatric epiglottitis.

The child appears pale, toxic, and lethargic and assumes a distinctive position—sitting up with the mouth open and the chin thrust forward. The child has difficulty swallowing, a muffled voice, drooling, fever, and extreme anxiety. Moderate to severe respiratory distress is evident. There is inspiratory and sometimes expiratory stridor, flaring of the nares, and inspiratory retraction of the suprasternal notch and supraclavicular and intercostal spaces. Within a matter of hours, epiglottitis may progress to complete obstruction of the airway and death unless adequate treatment is instituted. Epiglottitis is a medical emergency and immediate establishment of an airway by endotracheal tube or tracheotomy usually is needed. If epiglottitis is suspected, the child should never be forced to lie down because this causes the epiglottis to fall backward and may lead to complete airway obstruction. Examination of the throat with a tongue blade or other instrument may cause cardiopulmonary arrest and should be done only by medical personnel experienced in intubation of small children. It also is unwise to attempt any procedure, such as drawing blood, that would heighten the child’s anxiety because this also could precipitate airway spasm and cause death. Recovery from epiglottitis usually is rapid and uneventful after an adequate airway has been established and appropriate antibiotic therapy initiated.

**Lower Airway Infections**

Lower airway infections produce air trapping with prolonged expiration. Wheezing results from bronchospasm, mucosal inflammation, and edema. The child presents with increased expiratory effort, increased respiratory rate, and wheezing. If the infection is severe, there also are marked intercostal retractions and signs of impending respiratory failure.

**Acute Bronchiolitis/RSV.** Acute bronchiolitis is a viral infection of the lower airways, most commonly caused by the RSV.\(^{5,46}\) Other viruses, such as parainfluenza-3 virus and some adenoviruses, as well as mycoplasmas, also are causative. The infection produces inflammatory obstruction of the small airways and necrosis of the cells lining the lower airways. It usually occurs during the first 2 years of life, with a peak incidence between 3 and 6 months of age. The source of infection usually is a family member with a minor respiratory illness.

Older children and adults tolerate bronchiolar edema much better than infants and do not manifest the clinical picture of bronchiolitis. Most affected infants in whom bronchiolitis develops have a history of a mild upper respiratory tract infection. These symptoms usually last several days and may be accompanied by fever and diminished appetite. There is then a gradual development of respiratory distress, characterized by a wheezy cough, dyspnea, and irritability. The infant usually is able to take in sufficient air but has trouble exhaling it. Air becomes trapped in the lung distal to the site of obstruction and interferes with gas exchange. Hypoxemia and, in severe cases, hypercapnia may develop. Airway obstruction
may produce air trapping and hyperinflation of the lungs or collapse of the alveoli. Infants with acute bronchiolitis have a typical appearance, marked by breathlessness with rapid respirations, a distressing cough, and retractions of the lower ribs and sternum. Crying and feeding exaggerate these signs. Wheezing and crackles may or may not be present, depending on the degree of airway obstruction. In infants with severe airway obstruction, wheezing decreases as the airflow diminishes. Usually, the most critical phase of the disease is the first 48 to 72 hours. Cyanosis, pallor, listlessness, and sudden diminution or absence of breath sounds indicate impending respiratory failure. The characteristics of bronchiolitis are described in Table 36.2.

Evidence demonstrates multiple treatment modalities for bronchiolitis.\(^{45-47}\) Currently, use of hypertonic saline irrigation is thought to be most effective in a child without any other comorbidity.\(^{45}\) It is thought that the normal saline irrigation increases the child’s mucus transport and ability to excrete the mucus.\(^{45}\) In the past, guidelines suggested children with bronchiolitis be given albuterol and racemic epinephrine via nebulizer, but this is not always demonstrating the most effective outcome.\(^{46}\) The newest evidence suggests that the use of dexamethasone and epinephrine in the emergency department has been successful in decreasing hospital admissions of children with RSV bronchiolitis.\(^{47}\)

Infants with respiratory distress usually are hospitalized. Treatment is supportive and includes administration of supplemental oxygen if the oxygen saturation consistently falls below 90%.\(^{48}\) Evidence suggests that children with respiratory distress needing oxygen should first be given high-flow oxygen via a nasal cannula since it tends to increase oxygen saturation, increase comfort, and increase the overall respiratory condition.\(^{44}\) Often with young children a nebulizer is used to administer the steam or bronchodilator. Elevation of the head facilitates respiratory movements and avoids airway compression. Handling is kept at a minimum to avoid tiring. Because the infection is viral, antibiotics are not effective and are given only for a secondary bacterial infection. Dehydration may occur as the result of increased insensible water losses because of the rapid respiratory rate and feeding difficulties, and measures to ensure adequate hydration are needed. If the child is in respiratory distress and adequate hydration cannot be achieved, the child should receive intravenous fluids. Recovery usually begins after the first 48 to 72 hours and usually is rapid and complete. Adequate hand washing is essential to prevent the nosocomial spread of RSV.

**Signs of Impending Respiratory Failure**

Respiratory problems of infants and small children often originate suddenly, and recovery usually is rapid and complete. Children are at risk for the development of airway obstruction and respiratory failure resulting from obstructive disorders or lung infection. The child with epiglottitis is at risk for airway obstruction. The child with bronchiolitis is at risk for respiratory failure resulting from impaired gas exchange. Children with impending respiratory failure due to airway or lung disease have rapid breathing; exaggerated use of the accessory muscles; retractions, which are more pronounced in the child than in the adult because of more compliant chest; nasal flaring; and grunting during expiration. The signs and symptoms of impending respiratory failure are listed in Box 36.1.

**BOX 36.1 SIGNS OF RESPIRATORY DISTRESS AND IMPENDING RESPIRATORY FAILURE IN THE INFANT AND SMALL CHILD**

Severe increase in respiratory effort, including severe retractions or grunting, decreased chest movement

Cyanosis that is not relieved by administration of oxygen (40%)

Heart rate of 150 per minute or greater and increasing bradycardia

Very rapid breathing (rate 60 per minute in the newborn to 6 months or above 30 per minute in children 6 months to 2 years)

Very depressed breathing (rate 20 per minute or below)

Retractions of the supraclavicular area, sternum, epigastrium, and intercostal spaces

Extreme anxiety and agitation

Fatigue

**IN SUMMARY**

Although other body systems are physiologically ready for extraterine life as early as 25 weeks of gestation, the lungs take longer. Immaturity of the respiratory system is a major cause of morbidity and mortality in premature infants.

Lung development may be divided into five stages: embryonic period, pseudoglandular period, canalicular period, saccular period, and alveolar period. The first three phases are devoted to development of the conducting airways, and the last two phases are devoted to development of the gas exchange portion of the lung. By the 25th to 28th weeks of gestation, sufficient terminal air sacs are present to permit survival. It is also during this period that type II alveolar cells, which produce surfactant, begin to function. Lung development is incomplete at birth; an infant is born with only one eighth to one sixth the adult number of alveoli. Alveoli continue to be formed during early childhood, reaching the adult number of 300 million alveoli by 8 years of age.

Children with restrictive lung disease breathe at faster rates, and their respiratory excursions are shallow. An expiratory grunt is common as the child tries to raise the functional residual capacity by closing the glottis at the end of expiration. Obstruction of the extrathoracic airways often...
produces turbulence of airflow and an audible inspiratory crowing sound called stridor, and obstruction of the intrathoracic airways produces an audible expiratory wheezing or whistling sound. RDS is one of the most common causes of respiratory disease in premature infants. In these infants, pulmonary immaturity, together with surfactant deficiency, leads to alveolar collapse. BPD is a chronic pulmonary disease that frequently develops in premature infants who were treated with long-term mechanical ventilation.

Acute respiratory disease is the most common cause of illness in infancy and childhood. It accounts for 50% of illnesses in children younger than 5 years of age and 30% of illnesses in children between 5 and 12 years of age. Because of the small size of the airway of infants and children, respiratory tract infections in these groups often are more serious. Infections that may cause only a sore throat and hoarseness in the adult may produce serious obstruction in the child. Among the respiratory tract infections that affect small children are croup, bacterial tracheitis, epiglottitis, and bronchiolitis. Epiglottitis is a life-threatening supraglottic infection that may cause airway obstruction and asphyxia.

**REVIEW EXERCISES**

1. It is flu season, and although you had a flu shot last year, you have not had one this year. Imagine yourself experiencing an abrupt onset of fever, chills, malaise, muscle aching, and nasal stuffiness.

A. Which of these symptoms would lead you to believe you are coming down with the flu?

B. Because you hate to miss classes, you decide to go to the student health center to get an antibiotic. After being seen by a health professional, you are told that antibiotics are ineffective against the flu virus, and you are instructed not to attend classes but instead to go home, take acetaminophen for your fever, go to bed and stay warm, and drink a lot of fluids. Explain the rationale for each of these recommendations.

C. Explain why last year's flu shot did not protect you during this year's flu season.

2. Bacterial (e.g., *S. pneumoniae*) pneumonia is commonly manifested by a cough productive of sputum, whereas atypical (e.g., *Mycoplasma pneumoniae*) pneumonia, the cough is usually nonproductive or absent.

A. Explain.

B. A 4-month-old infant is admitted to the pediatric intensive care unit with a diagnosis of bronchiolitis. The infant is tachypneic, with wheezing, nasal flaring, and retractions of the lower sternum and intercostal spaces during inspiration.

Visit thePoint http://thePoint.lww.com for animations, journal articles, and more!
The major function of the lungs is to exchange oxygen and carbon dioxide to support the metabolic functions of the body’s tissues. The gas exchange function of the lungs depends on a system of open airways, expansion of the lungs, an adequate surface area for gas diffusion, and adequate blood flow through the pulmonary capillary bed.
Many types of disease are capable of disrupting the normal gas-exchanging function of the lungs. In some cases, the disruption is temporary, and in other cases, it is marked and disabling. In some people, it is due to a system-wide deterioration most probably from an acute trauma or injury. Frequently seen respiratory disorders that disrupt ventilation and pulmonary gas exchange are discussed in the following six sections:

- Physiologic effects of altered ventilation and gas exchange
- Disorders of lung inflation
- Obstructive airway disorders
- Interstitial lung disorders
- Disorders of the pulmonary circulation
- Acute respiratory disorders

It is important to realize that people with an underlying comorbidity such as chronic obstructive pulmonary disease (COPD) who then experience an acute event such as a blunt trauma of the thorax or lupus erythematosus will require more ventilatory assistance and cardiovascular support than those who have “normal” lung function and no autoimmune dysfunction. Also, any person with inflammation from sarcoidosis or an infection such as tuberculosis, or excessive bronchoconstriction from reactive airway disease, will be challenged if he or she acquires a condition that causes him or her to have acute respiratory failure.

**Physiologic Effects of Ventilation and Diffusion Disorders**

After completing this section of the chapter, you should be able to meet the following objectives:

- Define the terms hypoxemia and hypercapnia.
- Differentiate between the mechanisms causing disorders of ventilation and diffusion.
- Compare the manifestations of hypoxemia and hypercapnia.
